The mortgage interest deduction and its impact on homeownership decisions

Abstract

This paper examines the impact of the combined U.S. state and federal mortgage interest deduction (MID) on homeownership attainment, using data from 1984 to 2007 and exploiting variation in the subsidy arising from changes in the MID within and across states over time. We test whether capitalization of the MID into house prices offsets the positive effect on homeownership. We find that the MID only boosts homeownership attainment of higher income households in less tightly regulated housing markets. In more restrictive places an adverse effect exists. The MID is an ineffective policy to promote homeownership and improve social welfare.

JEL classification: H22, H24, H71, R21, R31, R52

Keywords: Homeownership, mortgage interest deduction, tax subsidies, land use regulation.

1 Introduction

One of the largest tax expenditures in the US, under federal law and some state law, is the mortgage interest deduction (hereafter, MID). It is justified as a means to broaden access to homeownership. There is some evidence, particularly from urban areas, that homeownership has important externalities. Hilber and Mayer (2009) find, however, that the positive externalities of homeownership may be confined to places with inelastic supply of housing. There is a large literature that suggests that in densely populated areas, homeownership is associated with lower crime rates, higher voting rates, more participation in collective action, etc.¹ Much earlier work has investigated the impact of the MID on national homeownership rates, but to the best of our knowledge, no study to date has sorted out the extent to which the MID impacts may vary depending on local housing supply conditions. Since the externalities appear to depend on location, it is appropriate to consider how the benefits depend on location. This is the main objective of this paper.

Using a measure of restrictions on new housing developed for 83 metro areas in the US (Saks 2008), we investigate how local housing market conditions and income status affect the way the MID influences household homeownership decisions. We find that the MID has no discernible impact in aggregate on U.S. homeownership outcomes, however, the MID has a perverse effect in highly regulated housing markets. Because the supply of housing in such areas is inelastic, rather than boosting homeownership attainment, much of the MID is capitalized into housing prices. At the higher housing price, certain types of households (e.g., down payment constrained households) opt out of the market for owner occupied housing, yet full capitalization of the subsidy and utilization of the housing stock can occur if the remaining market segment increases housing consumption in response to the subsidy. Only in markets with lax land use

¹ See, for example, Dietz and Haurin (2003) for an overview.

regulation does the MID have a positive impact on homeownership attainment, and the positive effect of the MID occurs only for higher income households. Our cost simulations suggest that a lower bound of the subsidy cost per converted homeowner amounts to a staggering \$28,397 per new homeowner per year.

The remainder of this paper is organized as follows. Section 2 discusses related research. Section 3 presents the economic theory of tax subsidies and housing markets and a stylized present value model to understand the impact of the MID on housing decisions according to local housing supply conditions. Section 4 describes the measure we use to capture the MID tax subsidy to homeowners. Section 5 details the data and sample issues, outlines our empirical approach and identification strategy, presents our empirical findings and discusses the quantitative significance. Section 6 concludes.

2 Related research

While the exclusion of imputed rental income of owner-occupied housing from taxable compensation is the key tax benefit to homeowners (Poterba and Sinai, 2008), in the presence of asymmetric tax treatment of property owners (i.e. landlords versus owner-occupiers), the MID also represents a sizeable tax break to owner-occupied housing. According to the tax law of the U.S. and most U.S. states, landlords are taxed on their net rental income. The interest on their mortgages is not a personal expense but an expense necessary to earn the rental income. Owner-occupiers do not have to pay taxes on their imputed rental income, yet, they can still deduct mortgage interest from their taxable income. A voluminous literature recognizes the importance of taking into account federal tax policy when examining housing market outcomes (e.g., Rosen, 1979; Dynarski and Sheffrin, 1985; Poterba, 1992; Turner and Smith, 2009). Early efforts to determine the impacts of removing the preferential tax treatment of owner occupied housing on homeownership attainment

include papers by Rosen (1979), Hendershott and Shilling (1982), Rosen *et al.* (1984) and Berkovec and Fullerton (1992) and, although the findings are not entirely conclusive, they suggest that the tenure choice impacts of removing the MID in isolation of other tax changes are likely to be small.

Several studies highlight the need to consider housing supply elasticities when examining the housing market impacts of tax reform (Capozza *et al.*, 1996; Green and Vandell, 1999). Capozza *et al.* (1996) maintain that the stock of prime residential land is inelastic, and thus altering the current tax treatment of owner-occupied housing will have price rather than quantity effects. In an examination of rent-price ratios in 63 metropolitan areas, Capozza *et al.* conclude that eliminating the mortgage interest and property tax deduction would reduce house prices by 2 to 13 percent depending on the metropolitan area. Using the Public Use Microdata Sample of the 1990 Census, Green and Vandell (1999) examine the likelihood of homeownership, controlling for state fixed effects in an effort to adjust for differing supply elasticities across states and find that replacing the MID with a revenue neutral tax credit would boost the national homeownership rate by about 5 percentage points.

Several papers document that the distribution of (primarily) federal housing tax benefits favors young and higher income homeowners and homeowners residing in regions with high incomes and high house prices (Glaeser and Shapiro, 2003; Sinai and Gyourko, 2004; Poterba and Sinai, 2008). However, high income households also tend to be higher wealth households and therefore they are likely to use equity financing to purchase their homes in the absence of the mortgage interest deduction (Gervais and Pandey, 2008), thus further suggesting that the MID may have little impact on homeownership attainment.

Two papers broach the subject of state mortgage subsidies. Consistent with Capozza *et al.*'s (1996) finding that the tax subsidies to homeowners primarily generate price effects,

Bourassa and Min (2008) find that the combined state and federal mortgage interest deduction has an adverse effect on homeownership attainment of the young. In contrast, in an examination of state mortgage subsidies, Glaeser and Shapiro (2003) report that state homeownership rates are unrelated to the size of state subsidies. Taken as a whole, existing research suggests that the MID may not be a particularly effective policy tool for boosting homeownership attainment. However, to our knowledge, no study to date has sorted out the extent to which the MID impacts may vary depending on local housing supply conditions, a task we turn to next.

3 Capitalization and the homeownership rate

3.1 Housing market dynamics

The impact of the MID on homeownership attainment depends on local housing supply conditions and, in the context of inelastically supplied housing markets in particular, the extent to which households are heterogeneous. To see why this is so, consider the standard model of housing market dynamics (Poterba, 1984). On the demand side, the MID may affect tenure choice and the quantity of housing consumed conditional on tenure choice. In the short run, the consumer's willingness to pay for new or expanded housing increases according to the present discounted value of the tax subsidy. The stock of housing is fixed in the very short run, thus the tax policy results in disequilibria in the housing market, and, depending on the extent to which a supply side adjustment is expected, the price of housing in the short run may rise by the full amount or by less than the full amount of the present discounted value of the tax subsidy.

In response to the demand-side housing market shock, the quantity supplied of owner-occupied housing may increase along three margins: the quantity of housing available through conversions of non-residential property, conversion of rental stock to owner-occupied use and the quantity of land used for housing. At one extreme, if the long run supply of owner-occupied

housing in a metro area is perfectly elastic (i.e., land use controls are very lax and developable land is available in abundance) the equilibrium purchase price of housing can be expected to return to its pre-subsidy level. The subsidy in this case results in an expanded housing stock, an increased homeownership rate, zero house price capitalization and a lower user cost of owner-occupied housing. At the other extreme, if tight regulatory constraints in a metro area make the owner-occupied housing stock perfectly inelastic, the subsidy will be fully capitalized into the purchase price of owner-occupied housing, the owner-occupied housing stock does not expand, and the subsidy does not increase the homeownership rate. The user cost of owner-occupied housing is unchanged. The capitalization of the subsidy into house prices represents a one-time windfall gain for existing homeowners. In elastically supplied markets no such windfall gain persists.

An adverse effect may arise in the presence of heterogeneous households and inelastically supplied housing markets. There are at least three types of households that may opt out of the market of owner-occupied housing when house prices rise. First, households facing down payment constraints have three choices when house prices rise: (i) exit the market, (ii) purchase at a later date once more wealth is acquired to meet the higher down payment amount, or (iii) own, but, to do so, accept increased leverage as the house price increase is rolled into a greater loan amount. In the event of rigid loan-to-value requirements, the household may not have the option of accepting higher leverage and may instead be priced out of the market. Second, households with relatively short expected durations may opt out of the owner-occupied market when house prices rise due to a subsidy-driven increase in transactions costs of owner-occupation. These transactions costs include realtor fees that are typically proportional to house values, financing costs and opportunity costs (Haurin and Gill, 2002) and are incurred at the time

of transaction, and therefore the annualized costs depend on the length of time in the housing unit. Third, households that are relatively risk averse may opt out of the market due to the subsidy-driven increase in house prices. By driving up house prices, an increase in the MID will require an increase in the amount of a household's portfolio allocated to owner-occupied housing, an increase in the LTV or both. A shifting of more assets into owner-occupied housing to meet a higher down payment amount decreases portfolio diversification and therefore increases the household's exposure to investment risk. Higher leverage similarly increases this risk. Greater exposure to investment risk all else equal is predicted to decrease the likelihood that households own (Turner, 2003; Hilber, 2005).

In this setting of inelastic supply and heterogeneous households certain types of households such as those detailed above may opt out of the market for owner occupied housing as the asset price of housing rises, while other households remain in the market and boost housing consumption in response to the tax break induced by the MID. The total physical quantity of housing does not change, yet full capitalization and utilization of the existing housing stock occur, despite a falling homeownership rate, as existing owners take up the slack by increasing housing consumption.

3.2 Present value model

In this section, we present a simple, stylized present value model to help illustrate the role of the housing supply elasticity in assessing the impact of a change in the mortgage subsidy rate (MSR) on homeownership attainment. Based on this model, we illustrate that in the case of perfectly elastic housing supply, an increase in the MSR unambiguously increases the likelihood of homeownership. In the case of perfectly inelastic housing supply, there is no clear theoretical impact of an increase in the MSR on the likelihood of homeownership. In this later case, we

further explore the possibility that the MSR effect may be adverse by simulating the impact of implementing a MSR in inelastic housing markets on the present value of a house purchase. We find that adverse effects can arise for a down payment constrained household, particularly at short durations and high transaction costs (as a percent of house prices).

Let P_1 be the purchase price of a unit house at time $t=1$. The household will buy if the discounted net present value (*NPV*) of the housing investment is positive, computed as the present value of the sum of the costs and benefits of owning a house relative to renting. For a holding period of N years we can express the *NPV* as:

$$NPV_t = -(1-\alpha_1)P_1 + \sum_{t=1}^N \left[\frac{R_t - (\psi_t + \pi_t)P_1(1 + \sum_{j=1}^t \pi_j)}{(1+r)^t} \right] + \frac{(1-\varphi)P_1(1 + \sum_{t=1}^N \pi_t) - L_N}{(1+r)^N} \quad (1)$$

where α_t represents the loan to value ratio and R_t is the real rental value of the housing services generated by the housing stock in period t . $\psi_t + \pi_t$ are the total after-tax outlays on the property as a percent of house value, ψ_t is the user cost of housing, and π_t is the nominal house price appreciation rate in period t . We define the user cost of housing in the usual manner (Poterba and Sinai, 2008):

$$\psi_t = (d + (1-MSR_t)\alpha_t r_t + (1-\tau)(1-\alpha_t)r_t + (1-\tau)\beta_t + (1-MSR_t)\delta_t) - \pi_t,$$

where d equals the depreciation and maintenance rate on the housing stock, $(1-\tau)(1-\alpha_t)$ equals the opportunity cost of the housing investment (taxable interest foregone on housing equity), τ represents the marginal tax rate on investment income, r_t equals the risk-free interest rate, β is the pre-tax risk premium for non-housing investment, and δ_t represents the property tax rate in period t . φ represents the transaction costs of selling the housing stock as a percent of the selling price, and L_N is the remaining loan balance at the end of the holding period (to be repaid at the time the house is sold).

The first term of equation (1) is the down payment amount. It is a cost incurred at the start of the holding period, N . The middle term is the net consumption value on the house (the rental value minus outlays), received in each year t , over the holding period, N . The third term is the amount received at the time the household sells the house, in year N , discounted according to the discount rate $(1+r)$.² Expressing the house price at time t as the product of P_1 times one plus the summation of the annual house price appreciation rates, π_t , from $j=1$ to $j=t$, allows us to embed the purchase price, P_1 , into the second and third terms of equation (1). We further embed the user cost term into the second term of equation (1), which we can do, since after-tax outlays are the user cost of housing net of nominal appreciation. To assess the impact of an increase in the MSR on the probability of homeownership, we differentiate equation (1) with respect to the MSR, which yields:

$$\begin{aligned} \frac{\partial NPV}{\partial MSR} = & -(1-\alpha_1) \frac{\partial P_1}{\partial MSR} + \sum_{t=1}^N \left[\frac{-\frac{\partial \psi_t}{\partial MSR} P_1 (1 + \sum_{j=1}^t \pi_j) - (\psi_t + \pi_t) \frac{\partial P_1}{\partial MSR} (1 + \sum_{j=1}^t \pi_j)}{(1+r)^t} \right] \\ & + \frac{(1-\varphi) \frac{\partial P_1}{\partial MSR} (1 + \sum_{t=1}^N \pi_t) - \frac{\partial L_N}{\partial P_1} \frac{\partial P_1}{\partial MSR}}{(1+r)^N} \end{aligned} \quad (2)$$

We assume that a one-time increase in the MSR will affect the purchase price, P_1 , not subsequent rates of house-price appreciation, π_t . To evaluate (2), first consider the case of a perfectly elastic housing stock, which implies zero long-run house price capitalization of an increase in the MSR and a reduced value of the user cost of owner-occupied housing. That is, when the housing stock is perfectly elastic, the equilibrium effects of the increase in the MSR are: $\partial P_1 / \partial MSR = 0$ and $\partial(\psi_t P_t) / \partial MSR < 0$. Imposing these conditions, equation (2) simplifies to:

² For simplicity we ignore capital gains taxes in equation (1). Since the Tax Reform Act of 1997, only capital gains on owner-occupied housing in excess of \$250K for single (\$500K for married filing jointly) are subject to tax. See Shan (2011) for a recent discussion.

$$\frac{\partial NPV}{\partial MSR} = \sum_{t=1}^N \left[\frac{-\frac{\partial \psi_t}{\partial MSR} P_1 (1 + \sum_{j=1}^t \pi_j)}{(1+r)^t} \right] > 0. \quad (3)$$

Equation (3) holds for sensible ranges of π_j (such that the nominal percentage increase in house value from the time of purchase to year t is not less than -100% in any given year t) and suggests that when the housing stock is perfectly elastic, an increase in the MSR in the first period unambiguously increases the *NPV* of a home purchase and the likelihood that a household will become a homeowner. This positive effect is independent of the holding period. Equation (3) only holds however, under current tax law, for households that itemize deductions and such households tend to be higher income. Thus equation (3) predicts that an increase in the subsidy will increase the likelihood that higher income households in elastic markets will own their housing.

Second, consider evaluating (2) in the case of a perfectly inelastic housing stock, which implies full long-run house price capitalization of an increase in the MSR and no change in the value of the user cost of owner-occupied housing. That is, when markets are perfectly inelastic, imposing the special case where $\partial P_1 / \partial MSR$ is different from zero and $\partial(\psi_t P_t) / \partial MSR = 0$ equation (2) can be written as:

$$\frac{\partial NPV}{\partial MSR} = -(1-\alpha_1) \frac{\partial P_1}{\partial MSR} + \frac{(1-\varphi) \frac{\partial P_1}{\partial MSR} (1 + \sum_{t=1}^N \pi_t)}{(1+r)^N} + \frac{-\frac{\partial L_N}{\partial P_1} \frac{\partial P_1}{\partial MSR}}{(1+r)^N} \quad (4)$$

Equation (4) cannot readily be signed. For sensible ranges of π_j (as noted above), the first term of equation (4) is negative.³ The second term is positive; however, its magnitude depends in

³ Note that full capitalization requires that $\frac{\partial P_1}{\partial MSR} = \sum_{t=1}^N \left[\frac{(\alpha_t r_t + \delta_t) MSR \times P_1 (1 + \sum_{j=1}^t \pi_j)}{(1+r)^t} \right] > 0$.

particular on the transaction costs of selling a home and the length of the holding period. The third term will be zero in the event that the household's loan terms are unchanged by the MSR-induced increase in house prices. This will be unlikely, however, if the household is down payment constrained; in this instance, the higher loan amount post-subsidy will cause the third term of (4) to be negative. The magnitude of this term will be greater at shorter durations for two reasons. In the early years of a loan, interest is front loaded into the payments, so that very little principle is paid off at short durations. Second, the denominator will be smaller for smaller N .

In order to determine if equation (4) can plausibly take on a negative value, we undertake the following thought experiment: What is the change in the NPV of a house purchase due to implementing a MID (of 26 percent) when full capitalization of the MSR into house prices occurs, households have a fixed amount – 20 percent of the initial purchase price – available for a down payment and households vary in their expected duration in their property? We simulate the effect of the introduction of the MSR in this setting for holding periods of 1 to 20 years and allowing the transaction costs to vary from 7 to 12 percent.⁴ The stylized story we are presenting is that the capitalization of the MSR into higher house prices is rolled into a larger loan amount post subsidy since the household has a fixed amount available for a down payment. While a potential homebuyer will ultimately benefit from the MSR-induced higher value of the home at the time of sale, all else equal, the potential buyer will also experience significantly higher financing costs as a result of the MSR-induced increase in house prices and in the loan-to-value ratio. For potential homebuyers with a short expected duration, the MSR-induced increase in

⁴ Haurin and Gill (2002) report a range of transaction costs estimates from the literature for ϕ , ranging from 6 to 13% of the sale price. Their estimate of ϕ is 3% of house value and 4% of income; however, as they note, the sample they use is short-duration-of-stay military households. Moreover to the extent that house prices tend to be proportional to income, the Haurin and Gill estimate may be regarded as constituting 7% of house values.

purchase price and financing costs brings about a decrease in the value of the investment, reducing the likelihood that they will own.

The simulation results are presented in the Appendix Table A3 and indicate that under the conditions of a perfectly inelastic market, the implementation of a MSR will *decrease* the probability of homeownership for down payment constrained households with expected durations of less than 5 to 7 years, depending on the value of φ . The simulation is suggestive of a potentially large negative impact of the MSR on the probability of homeownership, particularly since most households mortgage finance the purchase of a home and the median holding period in the United States is merely 6 years.⁵ While this is a stylized example, we think it is a plausible example for many potential homebuyers. It is not intended to prove that an adverse effect of the MSR must exist in inelastically supplied markets, but that an adverse effect may exist. Next we consider empirically testing for such an effect.

3.3 Measures of housing supply elasticity

There is ample evidence that indices of the restrictiveness of land use regulation are good proxies for the housing supply elasticity and thus for the potential for house price adjustment as a consequence of a demand shock or, conversely, expansion of owner-occupied housing through new construction. For example, Quigley and Raphael (2005) use a city-level index of regulatory stringency for California cities and relate this index to local house prices in 1990 and 2000. They document that more regulated cities have more expensive housing and a slower growth in housing stock. They confirm that these more regulated places also have a lower price elasticity of housing supply. In a similar vein, Saks (2008) demonstrates that locations with relatively few barriers to construction experience more residential construction and smaller increases in house

⁵ Statistic is based on data from the NAR for the years 2001 to 2006 (statistic provided by Walter Molony, Analyst for the NAR, April 2007).

prices in response to an increase in housing demand. Lutz (2009) examines the effect of a large exogenous shift in property tax burdens induced by a 1999 school finance reform in the state of New Hampshire. His estimates suggest that, in most of the state, municipalities with a reduced tax burden experienced a large increase in residential construction. In the area of the state near Boston, the region's primary urban center, however, the shock cleared through price adjustment. Lutz attributes these differing responses to differing housing supply elasticities, likely caused by spatial differences in regulatory restrictiveness. Finally, Saiz (2010) uses a current measure of regulatory restrictiveness – the Wharton regulatory index that captures the restrictiveness of regulation around 2005 – and relates this directly to measures of supply elasticity, demonstrating that more regulated metro areas have more inelastic supply.

In the empirical analysis that follows we employ a measure of regulatory restrictiveness – compiled by Saks (2008) – as our proxy for the responsiveness of the owner-occupied housing stock to changes in house prices. Saks (2008) derives a 'combined' measure of regulatory restrictiveness for the late 1970s and the 1980s by using the simple average of six independent surveys conducted during this time period. The index is scaled to have a mean of 0 and a standard deviation of 1. The index ranges from 2.21 for New York (most restrictive) to -2.40 for Bloomington-Normal, IL. Generally, desirable coastal metro areas such as New York, San Francisco, San Diego, Los Angeles or Boston are most tightly regulated, whereas metro areas in the Midwest and the South tend to have lax land use controls. However, there is considerable within-state variation in the regulatory index. For example, while most metro areas in California are tightly regulated, the index ranges from +2.1 for San Francisco to -0.32 for Orange County. Similarly, while metro areas in Texas tend to have relatively lax regulation controlling the expansion of the housing stock, the index ranges from -1.18 for Dallas to +0.98 for Tyler. The

most extreme difference can be found in the state of New York. Whereas, New York City tops the index table with +2.21, Buffalo-Niagara Falls is the second least tightly regulated place with an index of -1.96. See Saks (2008) and in particular her table A2 for further details.

For the purpose of our empirical analysis, the ‘Saks index’ has the important advantage – compared to more recent measures of regulatory restrictiveness – that it essentially pre-dates our sample period and, hence, is exogenous to (and not determined by) subsequent changes in tax policies and subsequent housing tenure decisions (and changes in homeownership rates) during the 1990s and 2000s.⁶ The ‘Saks index’ may also be preferable over geographical or physical constraints measures. Firstly, whereas tight regulatory constraints may always be binding and magnify price responses to demand shocks even if ample developable land is available, places with lax regulation and *comparably* little developable land may still have quite elastic supply. Various studies are indicative that geographical and physical constraints may only be affecting price responses to demand shocks in highly urbanized areas such as Boston or the Greater London Area (Lutz, 2009; Hilber and Vermeulen, 2010).⁷ Thirdly, in contrast to geographical constraints, regulatory constraints may also complicate or hinder the conversion of existing housing that is suitable for renter-occupation to housing that is more amenable for owner-occupation, thereby limiting the quantity supplied of owner-occupied housing.

For these reasons we conduct our empirical analysis with the index measure generated by Saks (2008). In this context Saks’ finding that in more strictly regulated metro areas house prices respond more strongly to changes in housing demand is particularly reassuring, as it supports our

⁶ More recent measures of regulatory restrictiveness, such as the Wharton Residential Land Use Regulation Index (WRLURI) from around 2005 (see Gyourko *et al.*, 2008) have the drawback that the level of regulatory restrictiveness may be caused by changes in homeownership rates during our sample period, which may in turn be affected by changes in the MSR.

⁷ Saiz (2010) considers the impact of the presence of water bodies and slopes steeper than 15 degrees. While such constraints significantly restrict coastal areas and areas with major mountain chains, many metro areas are neither coastal nor located near major mountain chains yet they likely vary significantly in their supply elasticity. Saiz also computed a direct measure of supply elasticity but this is based in part on the – for our purposes – endogenous WRLURI index.

implicit assumption that in more tightly regulated places (defined as in our study) the extent of capitalization of demand factors – e.g., the mortgage subsidy – is greater. In a further attempt to confirm our implicit assumption that house price capitalization effects are greater in more tightly regulated places, we conduct a simple test of the proposition that regulatory restrictiveness affects the extent to which the mortgage subsidy rate raises house prices within our sample. Table A1 in the Appendix reports the results of regressing the log of the house price index on the MSR (Panel A) and the house-price appreciation rate on the percentage change in the MSR (Panel B), respectively, controlling for year and MSA fixed effects as well as state and MSA time trends. Results are reported separately for highly regulated places (all metro areas with regulatory stringency of at least one standard deviation above the mean) and little regulated places (all metro areas with a regulatory stringency of at least one standard deviation below the mean). The results in both panels confirm that more regulated places have a much greater extent of capitalization of the MSR. The effect is between 4 and 12 times as large in the more regulated places and is statistically significant only in those places. While this is a preliminary and rather coarse look at capitalization, it is suggestive.

It is also worth noting that other studies (e.g., Quigley and Raphael, 2005, for the US; Hilber and Vermeulen, 2010, for the UK) that use different measures to proxy for regulatory stringency also come to the same conclusion; house prices react more strongly to demand shocks (i.e., the extent of house price capitalization is greater) in more tightly regulated markets and hence, all else equal, housing is more expensive in those markets. Finally, in addition to the regulatory control, the homeownership specifications we estimate control for housing stock composition in the Census tracts in which the households reside in order to capture at least in

part the other aspect of housing supply elasticity: the extent to which the existing rental stock can be converted to owner-occupied use.

4 Measuring the combined state and federal mortgage interest deduction

Our key variable of interest is the combined federal and state subsidy to homeowners through use of the federal and state (where applicable) mortgage interest deductions. While data reported in the PSID allows for the construction of each household's mortgage interest paid, itemization status and an approximation of the marginal tax savings the household receives from claiming the MID, using the household's actual marginal tax savings from the MID is not appropriate. The household's actual mortgage subsidy rate is a complicated function of the household's characteristics that also determine the likelihood of homeownership and would therefore be endogenous in a tenure choice model. Instead, we use a measure generated in the spirit of Cutler and Gruber (1996) that is correlated with the individual's mortgage subsidy rate, but exogenous and not correlated with the other determinants of homeownership. This measure is the NBER average state and federal combined mortgage interest subsidy rate, which is publically available and generated by the NBER based on a large, fixed, nationally representative sample of 1995 individual tax returns for each state and year, provided by the Statistics of Income Division of the U.S. Internal Revenue Service.

The NBER measure is generated as follows (Feenberg and Coutts, 1993): State and federal income tax liabilities owed by a large sample of taxpayers in each state in each year are calculated, holding the sample and income distribution fixed. The mortgage interest is then increased by 1 percent for each taxpayer, the state and federal taxes are recalculated, and the mortgage interest subsidy is generated as the ratio of the additional tax (savings) to the additional mortgage interest. The measure captures the tax savings from an additional dollar of mortgage

interest, or, equivalently, it is the marginal subsidy rate on mortgage interest. The average MSR in a given state and year is then computed by averaging over taxpayers by state and year.

The NBER measure has a number of desirable features. First, it varies only due to changes in the federal and state tax laws, not due to changes in income or other household characteristics of the taxpayer sample. Second, using a large micro sample to generate a taxpayer-level subsidy measure and then averaging over all taxpayers by state and year captures the non-linearity and richness in the tax code that would not be captured by use of a more aggregated approach (such as running state median income through a tax calculator). Moreover, because the NBER MSR measure is the simple average of all taxpayers' MSRs, we can derive the marginal effect of interest, the variation of the impact of the MSR by income status, without having an income-specific measure of the MSR: the marginal effects by income status controlling for the average MSR by income group and the marginal effects by income status controlling for the NBER MSR will be proportional (by a factor equal to the number of income categories).⁸ Third, using the average MSR in the state and year in which a household is observed provides an exogenous measure of the MSR for our household-level analysis.

There are two different effects of the MSR. First, there is the direct incentive effect of the subsidy for individuals. By use of aforementioned interaction terms, we can sort out the incentive effects by income group. Second, there is the indirect effect on house prices through the average market effect—essentially a reduced form effect. As presented in Section 5, we empirically distinguish the incentive versus market effects by controlling for supply conditions.

The MSR controls are capturing the incentive effect, and the degree of regulatory restrictiveness

⁸ To see this is so, consider a simplified example with two types of households: high income ($D_1=1$) and low income ($D_2=1$). Let X_1 equal the MSR received by high income households and X_2 equal the MSR received by low income households. Then the NBER MSR measure can be expressed as $X=(X_1 + X_2)/2$. A regression controlling for X_1 and X_2 (interacted with D_1 and D_2 , respectively) will yield coefficient estimates that equal 2 times the corresponding estimates from controlling for X (interacted with D_1 and D_2).

interacted with the MSR captures the market price effect. In models that fail to control for the supply elasticity, the MSR effect would be a combination of the incentive and market effects.

The variation in the combined state and federal NBER measure across states and within states over time can result from changes in the federal tax code, the state tax code or both. The federal subsidy rate is affected by changes in the federal tax code that alter income definitions, itemization status and marginal tax rates in particular. During the time period we examine, there are five major instances of federal tax law changes. These occur in 1986, 1993, 1997, 2001 and 2003. Reductions in marginal tax rates at the federal level may arise due to tax reform (TRA86) or fiscal stimulus (2001 and 2003 Bush era tax cuts), but in both instances reduce the value of the federal MID. In contrast, the 1993 and 1997 tax law changes increased marginal taxes rates, increasing the value of the federal MSR, but also put in places phase outs on some itemized deductions. Although states have a high degree of sovereignty in designing their tax codes, changes in the federal tax code may directly or indirectly trigger changes in state tax laws. For example, a change in federal marginal tax rates changes the value of deducting state taxes paid (income, sales, and property), which can affect the mix of tax instruments used at the state level.⁹ Changes in federal tax structure can also directly impact the value of a state-level MID. For example, eight states have reciprocal deductibility: federal taxes are also deductible from state taxable income (Fisher, 2007), and therefore changes in federal taxes paid affect the state marginal tax rate faced by the taxpayer and hence the value of the state MSR.

Some changes in the state MSR come about independently of changes in the federal tax code. States implement tax law changes when state fiscal crises arise or to mimic neighboring states' policies (Howe and Reeb, 1997). A series of papers has examined the impact of tax

⁹ A strong consensus exists in the literature that the federal deductibility of state taxes (income, sales and property) causes states to rely more heavily on these sources of revenue than on non-federally-deductible taxes (e.g., Feldstein and Metcalf, 1987; Feenberg and Rosen, 1986; Metcalf, 2011; Holtz-Eakin and Rosen, 1988).

competition between states on state tax law structure (e.g., Besley and Case, 1995).

Heterogeneity in state tax structure also arises due to variation in states' efforts to rely on taxes that allow an "exporting" of tax burdens to non-residents. This includes the aforementioned example of relying on tax sources that are deductible from federal taxable income. Other examples include the use of sales and business taxes that are expected to be shifted to residents of other states (Fisher, 2007).

In general, state income tax structures are not uniform across states and nor do they necessarily conform to the federal tax structure (Fisher, 2007, p. 414). Based on the variation in state tax structures and states' reactions to changes in federal tax structure, we expect that the variation in the MSR across and within states over time may be large. To determine if this is indeed the case, we examine a second NBER series, "the average net state mortgage interest subsidy by state and year," which we refer to as the state MSR. A state's MSR gives the mortgage subsidy rate arising from the state income tax structure. This NBER series is constructed in the same manner as the combined mortgage interest subsidy, but is derived from the state income tax liabilities only of the fixed 1995 taxpayer sample. Table 2 reports summary statistics for both the state MSR and the combined MSR series in each state for the time period we analyze (1984-2007).

Referring to Table 2, notice that there is significant variation in the state MSR across U.S. states: the average subsidy rate in Oregon, for example, is 8.12 cents for every dollar of mortgage interest, whereas the average subsidy rate in Alabama is only 3.56 cents. Comparing the minimum to the maximum values in Table 2, we see that out of the 34 states that have a state MSR, over half have a state subsidy rate that changes by at least 2 percentage points over this time period, and, in some states, the change in the state MSR is sizeable: in Arizona, New York

and Wisconsin the state MSR changes by 100% over the 24 year period under consideration.

Finally, note that for the 16 states without a state MSR, the combined MSR nonetheless changes, reflecting the change in the federal MSR subsidy received by the taxpayers in these states at different points in time.¹⁰

How much of the variation shown in Table 2 is common across states and hence would be swept up by year fixed effects? Figure 1 shows the variation in the state MSR by state over time.¹¹ No typical pattern emerges. The subsidy rises over time in some states and declines in others. Importantly, there is significant variation across states in the changes in the state MSR following instances of federal tax reform. For example, following TRA86, the state MSR rose in a number of states including Louisiana, Maryland, and Arkansas, but fell in others, such as Rhode Island and Minnesota.

5 Empirical analysis

5.1 Data and sample issues

This paper uses data from multiple sources. The primary data source is three decades of data from the ‘confidential version’ of the PSID, which is a longitudinal survey of families – from whom we (confidentially) know their Census tract of residence – that has been carried out continuously since 1968 and provides a unique opportunity to follow households over time and across space.¹² We select all PSID households observed from 1984 to 2007. We begin the panel in 1984 because this is the first year in which the PSID collects information on the household wealth

¹⁰ The following states are not represented in our PSID sample, but are included in Table 2 and Figure 1 for illustrative purposes: DE, IA, ME, MT, NE, NM, ND and VT.

¹¹ All graphs are normalized to a bandwidth of 5 percentage points, except OK, which has a vertical range from 0 to 7 percentage points. States not pictured do not have a state MSR during the time period considered, except CT. CT has a state MSR, but it is very small and graphically indistinguishable from zero if the regular bandwidth is applied.

¹² The PSID tract and MSA location indicators are confidential data from the PSID GEOCODE data files and can be obtained from the PSID under special contract. These data are not available from the authors.

holdings. Data are collected annually until 1997 and biennially after 1997, providing up to 19 observations per household.¹³ The data include (i) the original 1968 PSID core sample of 5,000 households selected as a random cross-section sample of the U.S. population with an additional low-income sample, and (ii) persons living within a household unit that enter the sample as a separate household when they form their own household. The PSID reconstituted its sample in 1997 by dropping 1/3 of the core sample, changing to biennial data collection, and reformatting sample weights. Thus, our sample includes only those households observed from 1984 through 2007, roughly 2/3 of the original core sample. All of the household data used in this study are collected in each year of observation, except wealth data. Prior to 1997, the wealth data are collected every 5 years. After 1997, they are collected with each survey. For the pre-1997 wealth data, we apply a linear function to impute annual estimates of total net wealth.

In addition to the ‘confidential version’ of the PSID, we use four secondary data sources – all publicly available – that report data at the tract, metro area or state level. The NBER provides the mortgage subsidy rate, our key variable of interest discussed above, as well as a property tax subsidy rate (generated similarly). Our second source is the Federal Housing Finance Agency (FHFA). From the FHFA we derive mortgage interest rate data as well as house price indexes.¹⁴ Specifically, the FHFA provides data on metropolitan and state average effective mortgage interest rates at the time of mortgage origination for conventional, single-family, non-farm loans. The data are from the FHFA’s Monthly Interest Rate Survey and are computed based on fully amortized loans. Refinances, non-amortized loans, and balloon loans

¹³ Due to missing data, we allow for an unbalanced panel in our analysis in order to include the greatest number of households. Our full regression sample underlying the specifications reported in Table 4 consists of 53,279 observations, which is roughly 67 percent of the fully balanced sample. 19 percent of households are observed every year, roughly 50 percent are observed in at least 14 years and 15 percent are observed for 5 years or less. The sample underlying the regulatory interaction specifications reported in Table 5 are slightly more unbalanced. Due to missing values this sample consists of 29,621 observations, which is roughly 60 percent of the fully balanced sample.

¹⁴ Until 2008, the most recent entity to generate the interest rate series was the Federal Housing Finance Board (FHFB). It was combined with OFHEO in 2008 to form the FHFA.

are excluded from the FHFA data, as are non-conventional loans (www.fhfa.gov). We use metro area data whenever available and state level data for PSID households that are not residing in one of the FHFA reported metro areas. The effective mortgage interest rate is the contracted rate adjusted for fees and charges. We use the mortgage interest rate data as part of the user cost controls in a robustness check of our main specifications. The house price index and appreciation data, used in Table A1 as well as in specifications controlling for the relative cost of homeownership, also come from the FHFA. FHFA produces public use house price indexes at the metropolitan and state level using a repeat sales methodology and data on single-family properties whose loans have been purchased or securitized by Freddie Mac or Fannie Mae over the years (see www.fhfa.gov). As with the FHFA interest rate data, we use the metro level indexes where available and the state level indexes for households that are not residing in one of the FHFA metro areas. The third source is the 1980 U.S. Census, which provides tract-level data on housing stock characteristics. The specific variables we examine include the share of housing units in the tract that are single-family and the share of units that are in multiplexes (structures with 5 or more units). We use the 1980 composition of the housing stock as it will be exogenous in an analysis of the probability of homeownership post 1980. Finally, as noted in Section 3.3, we use the metropolitan-level regulatory index generated by Saks (2008) as a measure of the housing supply inelasticity. We link all these data to PSID households using PSID geographic location information.

The final sample includes 4,197 households corresponding to 53,279 household-year observations residing in metropolitan and non-metro areas for the base empirical specifications, and 2,620 households corresponding to 29,621 household-year observations residing in metropolitan areas for which we have Saks (2008) regulatory index data. Roughly 2.5 percent of

households move to a different state and 4 percent of households move to a different MSA in any given year. All dollar amounts are adjusted to 2007 dollars using the urban Consumer Price Index. All analysis is weighted using the PSID 2005 sample weights.¹⁵

5.2 Empirical approach

We estimate the following base specification for household i in location j at time t as a linear probability model:

$$\Pr(\text{own}_{ijt}) = \alpha_0 + \alpha_1 \text{MSR}_{jt} + X_{it}' \beta + L_{jt}' \delta + D_i' \lambda + e_i, \quad (5)$$

where MSR is the mortgage subsidy rate, which is expected to have a positive coefficient to the extent that it facilitates homeownership. The household's MSR varies over time even if the household does not move at all or only moves within state. This is because the MSR varies within state over time. X is a vector of household characteristics that vary over time, L is a vector of time-invariant and time-varying location controls and D is a vector of individual fixed effects. The vector of time-varying household characteristics includes controls for total family income, total net wealth, age of head, marital status, children, and unemployment of head and spouse if present. We control for income by use of three income categories: low, moderate or high income. A low-income household is one whose annual income is less than or equal to 80 percent of state median income; moderate-income households include households with incomes between 80 and 120 percent of state median income, and high-income households are those with incomes above 120 percent of state median income.¹⁶ The vector of location characteristics

¹⁵ The PSID sample is not representative of the U.S. population without the application of sample weights. The post-1997 weights are stratified to the U.S. population according to data from the Current Population Survey. See Heeringa and Connor (1999) for more discussion. We use the 2005 combined family weight because the more recent 2007 weight is preliminary and not available for as many households as the 2005 weight.

¹⁶ We use state median income data from the U.S. Census Bureau Table H-7, which provides annual median income estimates by state from 1984 to 2007, based on the Current Population Survey. Regarding the income classifications, note that state homeownership assistance programs, such as Florida's State Housing Initiatives Partnership Program (SHIP), the largest state housing trust fund, use these income definitions. For example, see

includes tract-level housing stock controls (the share of housing units that are single family units and the share of housing units in multiplexes), MSA fixed effects and state fixed effects. The rationale for including both MSA- and state fixed effects is that not all households reside in MSAs. The state fixed effects provide location controls for those places. Also, there could be unobservable time-invariant effects at the MSA and state level. We also estimate equation (5) with MSA and state time trends to control for unobserved factors at the MSA and state level that may affect homeownership attainment and may be changing over time. We estimate (5) with a cluster correction to generate standard errors that are robust to heteroskedasticity and clustering on two dimensions: households and ‘state \times year’. We simultaneously cluster on these two dimensions to address the possibility that the errors may be serially correlated or spatially auto-correlated at the state level. While clustering on households deals with the serial correlation issue, clustering on ‘state \times year’ addresses the possibility of spatial auto-correlation at the state level.¹⁷ We also run specifications that allow for a differential impact of tax subsidies depending on the household’s income by interacting MSR with income status.

One advantage of estimating equation (5) as a fixed effect model is that household fixed effects capture all unobserved heterogeneity in household characteristics – such as race/ethnicity of the household head – that are time invariant. To the extent that households don’t move, the fixed effects also capture time invariant location characteristics (at neighborhood-, municipality-, county-, state-, region-, and national-level). However, households do move across space and we observe such changes in our panel. As a result, we also include the location controls discussed

<http://www.floridahousing.org/Home/HousingPartners/LocalGovernments>. The U.S. Department of Housing and Urban Development’s HOME program, which supports homeownership, defines low income as 80 percent of MSA median income (<http://www.hud.gov/offices/cpd/affordablehousing/lawsandregs/index.cfm>).

¹⁷ The reported standard errors are similar to those generated in specifications that only use a Huber-White sandwich estimator to correct for heteroskedasticity and those resulting from specifications that only cluster on households but not on ‘state \times year’ groupings. Clustering by state is problematic in our empirical setup because households do move across states over time so the panels are not nested within state clusters (but they are nested within a given state and year).

above. Regarding total net wealth, note that changes in net asset wealth are driven in part by changes in income. Hence, once we control for fixed effects and household income, the impact of household net wealth on homeownership attainment can be expected to be quite limited.

The use of state fixed effects in our empirical setup implies that we identify the effect of the MSR on the propensity to own off of variation in the MSR over time within states as well as across states. As noted above, the household's MSR varies over time even if the household does not move at all or only moves within state. This is because the MSR varies within state over time. The household fixed effects allow us to also identify off of across state moves. Being able to use across state moves in addition to within state moves is arguably an added benefit of our approach, particularly since across state moves are often associated with substantive changes in the MSR. However, importantly, the household fixed effects do not preclude us from identifying off of within state moves or non-moves. In fact, most of the variation in the MSR of households is driven by within state changes of the MSR over time, which affect both within state movers and non-movers. Only roughly 3 percent of all changes in the MSR are driven by across state moves. We document the relevance of the two sources of variation (i.e. arising from changes in the MSR within state over time or arising from moves across states at different points in time) in the result-section below.

One concern with across state movers is that they may not be similar over time and across states and this may lead to a selection bias. In particular, households who move across states may be different from the rest of the population (i.e., non-movers and within-state movers), and it may be the characteristics of the across-state movers that explain our estimated effects rather than the subsidy rate itself. To address this concern, we check for whether or not our results are being driven by across state moves. To do this, we re-estimate our core specifications but

additionally include ‘household \times state’ fixed effects, in order to control for all state-specific unobserved characteristics of across state movers.¹⁸ Put differently, for each household we only exploit within state variation in the MSR, ignoring variation that arises from across state moves.

To explore the impact of regulatory restrictiveness, we estimate the following specification for household i in location j at time t , again, as a linear probability model:

$$\Pr(\text{own}_{ijt}) = \alpha_0 + \alpha_1 \text{MSR}_{jt} + \alpha_2 \text{MSR}_{jt} * \text{reg}_{jt} + \alpha_3 \text{reg}_{jt} + X_{it}' \beta + L_{jt}' \delta + D_i' \lambda + e_i, \quad (6)$$

where reg equals the value of the regulatory index – scaled to have a mean of zero and a standard deviation of 1 – with higher values of the index indicating greater regulatory restrictiveness and hence more inelastic housing supply. The theoretical considerations presented in Section 3 suggest that $\alpha_2 < 0$: the positive impact of the subsidy on homeownership attainment ought to be weaker (and the negative impact stronger) in more regulated metro areas. Note that reg_{jt} varies in the panel even though our regulatory proxy is time-invariant and only varies by location. This is because reg_{jt} varies as households move between metro areas and thereby move from more to less restrictive places and vice versa. We also run specifications where the regulatory index is interacted with the MSR and with the income status in order to investigate the extent to which different income groups are differentially affected by the mortgage subsidy rate in different regulatory environments. As with estimating equation (5), we estimate (6) simultaneously clustering on households and ‘state \times year’.

Missing from the analysis so far is a control for the relative cost of homeownership: the cost of housing services in the owner mode relative to the cost of housing services in the rental

¹⁸ To see how we construct the household \times state fixed effects, consider an example. Suppose a household resides in two states during our observation period: the household is observed living in CA and then moves to TX. We create two mutually exclusive indicator variables for this household: the first equals one in each year the household is in CA and zero otherwise. The other equals one in each year the household is in TX and zero otherwise. These fixed effects ensure that we only identify off of changes in the MSR that are *not* due to households moving across states.

mode. In studies of homeownership, the annual cost of housing services in the owner mode is generally approximated as the user cost of housing, which is a household-specific variable measuring the expected consumption value of the housing services from purchasing a home. The user cost is the sum of depreciation and maintenance costs, the after-tax opportunity cost of the down payment, the after-tax mortgage interest payments and after-tax property tax payments minus the expected, nominal capital gain on the housing structure (Poterba, 1984). Of these components of user cost, equations (5) and (6) control for the mortgage interest tax break using the NBER SOI data (MSR). As a robustness check, we also run the models in equation (6) adding controls for additional determinants of user cost: the FHFA reported effective mortgage interest rate, the NBER property tax subsidy rate and the FHFA contemporaneous house price appreciation rate as well as the price of rental housing, which we control for as the average annual rent in the city and year in which the family is observed.¹⁹

5.3 Results

Table 1 presents population weighted summary statistics for the full sample and the regulatory restrictiveness sub-sample. Table 2 is discussed in section 4. Table 3 summarizes the sources of variation in the MSR. Table 3, Panel A, reports the distribution of moves by type (within state and across state) for the full regression sample according to 5 possibilities: no change in the MSR, a change in the MSR, and then by three different magnitudes of change in the MSR. Categories (1) and (2) in Table 3 show that there are 50,216 household-year observations in the panel for which we observe data from one year to the next. Of these, 49,873 household-year observations experience a change in the MSR from the prior year and 343 do not.

¹⁹ The remaining terms in UC, depreciation and maintenance, are each typically set to a value of 0.02 (see e.g. Poterba, 1992), and thus would be part of the constant in an estimation. For the rent data, we compute the average self-reported rent in the PSID in the city and year in which we observe the household. For households residing in non-metropolitan areas or metropolitan areas with a relatively small sample size (less than 100 PSID respondents), we compute a regional rent based on the metropolitan areas being located in one of the nine Census Divisions.

Among the 49,873 household-year observations that experience a change in the MSR since the previous year, the vast majority, 97 percent, are *not* across state moves. Category (1) shows that some moves occur both within and across states, even though the MSR is unchanged. Category (2) shows that we observe 9,161 household-year moves that are accompanied by a change in the MSR. Of these, 7,653 are within-state moves and 1,508 are across-state moves. Note that among identified moves in category (2), 84 percent are within-state moves (this percentage may actually be a little higher since we cannot identify *within Census tract* moves).²⁰ When we consider the distribution of moves by type for varying degrees of change in the MSR, we see that only for the most substantial changes in the MSR (5 percent or higher) as shown in category (5), the across-state moves dominate the sample, but they are not the only source of variation. Of the 372 household-year observations which experience a change in the MSR greater than 5 percent from one year to the next, 55 percent are associated with across state moves, the remaining changes are either associated with within state moves (6 percent) or non-moves across tracts (39 percent). Households that elect not to move when the MSR changes also provide identification of the impact of the MSR on homeownership attainment. In fact, in principle non-movers can also change their housing tenure: renters can buy their rental property and homeowners can sell and lease back their homes. Panel B of Table 3 documents the equivalent statistics for the regression sample with information on regulatory restrictiveness. Overall, Table 3 illustrates that the variation in the subsidy arises mainly from (i) within state changes in the MSR over time

²⁰ We use 1980 Census tract indicators and boundaries from the confidential PSID to identify whether households moved in any particular year or not. A household is identified as a mover-household if a change in the tract occurs. It is identified as an across-state mover if the state changes as well. We cannot categorize moves that occur within tract. While the PSID does have variables that indicate moves, these indicators are not consistent over the 1984 to 2007 time period. Since all within Census tract moves are also within state moves, Table 3 may underrepresent the share of within state moves. It is important to emphasize that while Table 3 does not capture within Census tract moves, our empirical analysis does. We pick up every move for which there is a change in tenure status. That is, if a household changes tenure status within tract over time, we capture that move through a change in tenure status.

(affecting both within state movers and non-movers) and to a lesser extent from (ii) time-varying across state differences (affecting across state movers).

Table 4 reports the results for the baseline estimations on the full PSID sample. Column (1) provides results for the specification that includes only the MSR, household controls, and household fixed effects. Column (2) then adds locations controls (the housing stock variables, MSA fixed effects and state fixed effects). Column (3) adds year fixed effects, column (4) adds state time trends and column (5) adds MSA time trends. Column (6) includes all these controls and allows for separate effects of the MSR by income group. Across all six specifications, the key variable of interest, the MSR, has no statistically significant impact on the likelihood of homeownership, not even for the highest income households, in column (6), who tend to receive the greatest tax breaks from this feature of the tax code. This result is consistent with Glaeser and Shapiro (2003) and suggests that, on aggregate, this very costly tax subsidy to U.S. homeowners has no discernible impact on the likelihood of homeownership attainment.

The control variables all generate results that are sensible, intuitive and robust across all models. Income, wealth, age, being married and having children all positively impact the likelihood of homeownership, with income and being married having particularly large impacts: based on the coefficients reported in column (5), high-income households are 13.8 percentage points more likely to own than low-income households; being married increases the likelihood of homeownership by 17.1 percentage points. An episode of head or spouse unemployment lowers the likelihood of homeownership by 4 and 3.2 percentage points, respectively. The location controls indicate that the composition of the housing stock matters for homeownership attainment: a greater fraction of single family units boosts homeownership attainment whereas a greater fraction of multiplexes lowers it.

Table 5 reports results for specifications where the MSR is interacted with regulatory tightness and with income status. Our proposition, theoretically motivated in Section 3, is that in more regulated places (with inelastic supply), the tax subsidies get capitalized into house values rather than expand the (owner-occupied) housing stock and thereby have little impact on homeownership attainment, or, may in fact have a negative impact, for example, because homeownership becomes comparably less attractive for down payment constrained households with short expected durations in their homes. Columns (1) to (3) allow for the impact of the MSR to vary by regulatory restrictiveness on the full sample for which we have regulatory data, with column (2) adding state time trends and column (3) also adding MSA time trends. Columns (4) and (5) further decompose the impact of the MSR on homeownership attainment by interacting the subsidy with regulatory restrictiveness and with income status. Column (4) adds state time trends to the standard controls; column (5) additionally adds MSA time trends. Columns (6) and (7) replicate the specifications reported in columns (3) and (5) except that columns (6) and (7) additionally control for household \times state fixed effects. The last two specifications allow us to test to what extent our results may be driven by across state movers who may be quite different from the rest of the population. The inclusion of household \times state fixed effects controls for all state-specific unobserved characteristics of across state movers. Put differently, for each household we only exploit within state variation in the MSR, ignoring any variation that arises from across state moves.

Columns (1) to (3) indicate that the MSR has no statistically significant impact on the likelihood of owning if a household lives in a metro area with an average degree of regulatory restrictiveness. If a household lives in a place with relaxed land use controls (with a regulatory index below 0) the MSR will have a positive impact on homeownership attainment, whereas the

effect is negative in more tightly constrained locations (with a regulatory index above 0), in line with our theoretical conjectures. According to column (3), evaluating the regulatory index at its sample mean of 0.191 suggests that the marginal effect of a one standard deviation increase in the MSR is negligible, increasing the homeownership rate by 0.03 percentage points. Evaluating the regulatory index at its extreme values of -2.4 (Bloomington-Normal, IL) and 2.21 (New York, NY) generates the following range: a one standard deviation increase in the MSR increases the likelihood of homeownership by 3.5 percentage points in the least regulated place and reduces the same by 2.7 percentage points in the most tightly regulated place.

Referring to columns (4) and (5), we see that a further decomposition is insightful. It reveals that the impact of the subsidy on homeownership attainment by regulatory status varies considerably by income status. Our findings indicate that the subsidy has no effect on the likelihood that low-income households will attain homeownership, regardless of the regulatory status of the city in which they reside. We conjecture that this result is a combination of two stylized facts: housing markets are segmented and very few low income households itemize.²¹ Previous research indicates that housing markets tend to be segmented at the sub-metro level by house value (e.g., Case and Mayer, 1996). Low income households, which typically are non-itemizers, tend to own lower valued houses and live in housing tracts with other lower income households (Belsky and Duda, 2002), suggesting that for middle or high income households, the low-income housing tracts may not be a substitute for the higher end housing in tightly regulated markets. To the extent that there is indeed no (or very little) substitutability between low income and higher income housing and the MSR generates little benefit for low-income homeowners,

²¹ Even among low-income homeowners itemization rates are low. For example, using 2004 data from the Survey of Finances combined with NBER TAXSIM data, Poterba and Sinai (2008) report in their Table 2 that only 23 percent of low-income homeowners (those earning less than \$40K in 2003) itemize whereas over 98 percent of high income homeowners do (those earning \$125K or more).

economic theory predicts that the MSR may not affect the demand for lower end housing and thus will have no effect on the price of lower end housing, independent of the supply price elasticity proxied by our regulatory constraint measure. Taking these considerations into account, our finding that the MSR has no effect on homeownership attainment of low income households appears to be quite plausible.

The coefficients on the interaction terms for moderate- and high-income households in columns (4) and (5) are statistically significant and meaningful. Consider column (5) that includes MSA time trends in addition to state time trends. Evaluating the regulatory index at its extreme values generates the following range for moderate-income households: a one standard deviation increase in the MSR increases the likelihood of homeownership attainment by 3.6 percentage points in the least regulated location and reduces it by 3.3 percentage points in the most tightly regulated place. For high-income households, the impact of a one standard deviation increase in the MSR on the likelihood of homeownership ranges from a 4.1 percentage point increase (least restrictive) to a reduction of 3.8 percentage points (most restrictive).

Columns (6) and (7) report the findings of our robustness check whereby we include ‘household \times state’ fixed effects to gauge to what extent our results may be driven by across state movers. The coefficients of the two specifications with ‘household \times state’ fixed effects are qualitatively unchanged and quantitatively very similar to the corresponding specifications without the ‘household \times state’ fixed effects, reported in the corresponding columns (3) and (5). These findings imply that our key findings are not driven by *across state movers* who may not be similar over time and across states.

Regarding all the other results from Table 5, the household and location controls continue to be intuitive, plausible and robust across samples and specifications; the coefficient estimates

are available from the authors upon request. Finally, as a robustness check, we re-estimate the specifications in Table 5 controlling for additional components of user cost: the NBER combined state and federal property tax subsidy rate, the FHFA effective mortgage rate, and the FHFA metropolitan house price appreciation rate as well as the price of rental housing. The results are reported in the Appendix Table A2. The additional controls have a negligible impact on our key findings. Of the controls, only the coefficient on rent is statistically significant across all specifications and suggests that a one standard deviation increase in local rents, holding the user cost of owner-occupied housing constant, increases the likelihood of homeownership by 1.7 to 1.8 percentage points in all specifications. The property tax subsidy rate is marginally statistically significant only in column (7). The quantitative impact is relatively small: a one standard deviation increase in the property tax subsidy rate increases the propensity to own by 1.9 percentage points. We should interpret these findings with some caution however as two of the additional controls are subject to endogeneity concerns. The property tax rate is affected by house prices; places with greater housing wealth can set lower property tax rates, all else equal, and can still offer better local public services. At the same time an increase in the local homeownership rate may cause higher prices for owner-occupied housing. Hence, homeownership may affect property tax rates via house prices – reverse causation may be present. In a similar vein, if the homeownership rate increases, demand for mortgage credit strengthens as well. This in turn can raise mortgage interest rates. Again, reverse causation may be present. For all these reasons we only report these results as an Appendix Table (A2) rather than as our main specifications.

5.4 Quantitative effects

One way to gauge the cost of the MID is to compute the cost per net new homeowner created by the MID. To do so, we first determine the net number of households that are hypothetically moved into homeownership as a result of the mortgage interest subsidy. Using the specifications in Tables 4 and 5, we compute the probability of homeownership for each household with and without the mortgage subsidy. If in a given year the subsidy moves a household from a less than 50 percent likelihood of homeownership to a likelihood that exceeds 50 percent, the household is counted as moving from renting to owning. If the household's likelihood of homeownership decreases from above 50 percent to less than 50 percent as a result of the subsidy, this household is counted as moving from owning to renting. If the household does not experience a change in the likelihood of homeownership that crosses the 50 percent threshold, the household is counted as not having experienced a change in its tenure status.

We then compute the fraction of the sample that falls into each category: moving from renting to owning, moving from owning to renting, or having no change in tenure status. The net impact is computed as the percent of the sample moved into homeownership minus the percent of the sample moved out of homeownership, as defined above, as a result of the MID. Table 6, Panel A, reports these results by specification. Notice that for the U.S. on average, based on the econometric results in Table 4, this exercise suggests a net *negative* impact of the MID on the likelihood of homeownership (although the effects are all not statistically significant), whereas all but one specification reported in Table 5 imply a relatively small positive (and statistically significant) impact. (The specification in column (6) of Table 5 implies a very small but statistically significant negative net effect.) Our core specification reported in column (5) of Table 5, which allows the impact of the MID to vary by regulatory restrictiveness

and by income status, results in a net positive gain in the number of homeowners by 3.2 percent, and this is the estimate we proceed with to compute the subsidy cost per net additional homeowner.

There are an estimated 115 million households in the US in 2010 (the most recent Census Bureau estimate available).²² Hence, specification (5) in Table 5 implies that the subsidy in any given year generates 3.68 million new homeowners in the United States (3.2 percent times 115 million). At an estimated total cost of 104.5 billion in 2011 (Office of Management and Budget, 2010), the subsidy per converted homeowner thus amounts to a staggering \$28,397 per year.²³ The (non-significant) coefficients on the MID-variable reported in the various specifications in Table 4 – if taken at face value – all imply that the tax payer may spend 104.5 billion in 2011 with the overall net effect being that *fewer* households own, as a consequence of the MID. More importantly, the estimated figures may be lower bound because ‘inertia’ or moving costs may prevent households from changing their tenure status, even if it were per se optimal to do so. This is because the moving cost may exceed the gains associated with the tenure change. In practice, most households will only question their optimal tenure status when they have to relocate for other reasons. Hence, the net addition of homeowners, as a consequence of the MID, may be significantly less than the 3.68 million that our core simulation implies. To the extent this is true; the subsidy per converted homeowner may be a multiple of \$28,397 per year.

Table 6, Panel B, documents the implied average change in the propensity to own for low, moderate and high income households as a consequence of the implementation of an MID

²² See www.census.gov/population/projections/nation/hh-fam/table1n.txt.

²³ The costs are substantially higher according to the results reported in column (7) of Table 5, which allows the impact of the MID to vary by regulatory restrictiveness and by income status, net of the influence of across state movers. This specification implies a net positive gain in the number of homeowners of 0.7 percent, suggesting that to move one renter household into homeownership through the MID costs US taxpayers \$129,814 in foregone tax revenue annually.

of 26 percent – the sample average. Results are reported separately for tightly and loosely regulated places (corresponding to the categorization in Table A1). Whereas in these polar cases the effects of the MID on the propensity to own are never statistically significant for low income households, the effects for moderate and high income households are not only statistically significant but also quantitatively meaningful: In the most tightly regulated places the introduction of the MID reduces the propensity to own, depending on the specification and income category (moderate or high), by between 18 and 28 percent. In the least regulated places the propensity to own increases by between 13 and 28 percent.

6 Conclusion

This paper provides a first look at the impact of the combined state and federal mortgage interest tax subsidy on homeownership attainment taking into account housing supply conditions via a measure of regulatory restrictiveness in local housing markets. We find that the MID has no statistically significant impact on homeownership attainment in aggregate. However, the MID does have an impact on individual homeownership decisions – both positive and negative – depending on the restrictiveness of land use regulations at the place of residence and the income status of the household: In places with more elastic housing supply, the MID has a positive effect on homeownership attainment, but only for higher income groups. In more restrictive places, the mortgage tax subsidy has a significant adverse impact, again only for higher income groups. The MID has no impact on the homeownership attainment of low-income households, regardless of regulatory status. We speculate that this is because the housing market within a city tends to be segmented by income and the MID only provides a tax subsidy to the relatively higher income households that itemize. Consequently, we expect that lower income housing will generally not experience house price changes due to changes in the subsidy.

It has previously been documented that the MID is a regressive feature of the tax code in terms of the annual distribution of tax benefits, which go disproportionately to higher income households (e.g., Poterba and Sinai, 2008). This paper documents other dimensions along which the MID is a regressive policy: In more elastically supplied housing markets, where the MID does have a positive impact on homeownership attainment, the positive effects are confined to moderate and high income households, and the impact is stronger for high income households. Moreover, we expect that the MID boosts housing consumption of these households since the tax break reduces the user cost of housing of high income households disproportionately more due to their higher marginal tax rates. In the more regulated markets, the MID tends to be capitalized into higher house prices, and thus represents a one-time wealth transfer to existing homeowners from taxpayers who do not currently own. Existing owners tend to be older and have accumulated more wealth than existing renters who either cannot own (households with binding down payment constraints) or do not want to own (households with short expected durations).

One argument in favor of the MID is that it may help to increase homeownership attainment in highly urbanized (inner city) areas. These areas are often confronted with underperforming public schools, lack of social capital and poor governance and recent research has highlighted that positive externalities associated with homeownership may help local communities to improve along those dimensions (Hoff and Sen, 2005; DiPasquale and Glaeser, 1999; Hilber and Mayer, 2009; Fischel, 2001). However, our research suggests that the MID decreases rather than increases homeownership attainment in the typically more tightly regulated urbanized places. In the less urbanized places with lax land use controls, the MID does have a positive impact on homeownership attainment (at least for higher income groups). However, recent research suggests that in these ‘elastically supplied’ places homeownership may generate

few or no positive externalities. This is because in the absence of house price capitalization effects, homeowners have few incentives to invest at the local level, for example, in local public schools (Hilber and Mayer, 2009) or in local social capital (Hilber, 2010). We conclude that the MID is a costly and ineffectual policy for boosting homeownership and social welfare.

To fully understand the distributional and efficiency impacts of the MID, future work might examine its impact on the “over-consumption” of owner-occupied housing by income and regulatory status. This paper examines only a portion of the total subsidy to homeowners; imputed rent is untaxed, capital gains are untaxed for most households and property taxes are tax deductible. Another area for future research is to explore the extent to which these other tax subsidies to homeowners also generate unintended consequences, particularly, in more inelastically supplied housing markets.

PANEL B										
Sample with information on regulatory restrictiveness (Table 5)										
	(1)		(2)		(3)		(4)		(5)	
	No change in MSR		Any change in MSR		Change in MSR >1%		Change in MSR >3%		Change in MSR >5%	
	# obs.	in %	# obs.	in %	# obs.	in %	# obs.	in %	# obs.	in %
No move across tract	124	88.6	22,051	80.2	6,046	74.5	1,765	70.3	105	41.8
Moves across tract <i>within state</i>	14	10.0	4,597	16.7	1,401	17.3	398	15.9	17	6.8
<i>Across state</i> moves	2	1.4	859	3.1	664	8.2	348	13.9	129	51.4
Total number of obs.	140	100	27,507	100	8,111	100	2,511	100	251	100

Notes: We use 1980 Census tract indicators to identify whether households moved in any particular year or not. A household is identified as a mover-household if a change in the Census tract occurs. It is identified as an across-state mover if the state identifier changes as well. We cannot categorize moves that occur within tract and hence the above statistics slightly underrepresents the fraction of within-state moves. The probability that a household moves tract from one PSID period to the next is 18.3 percent in the full regression sample and 19.8 percent in the sample with information on regulatory restrictiveness. The total number of observations reported in this table differs from the regression samples as this table considers *changes* in the mortgage subsidy rate (MSR) from one year to the next for all observations in the regression sample with available information. The full regression sample consists of 53,279 observations. We do not compute changes in the MSR for the 2,342 observations in 1984 as 1983 is not in our regression sample. For a further 721 observations no Census tract information is available for the previous year, resulting in a total of 50,216 (=343+49,873) observations in Table 3, Panel A. The regression sample used in Table 5 consists of 29,621 observations; of these 1505 are for 1984. A further 469 observations do not have Census tract information for the previous year, resulting in a total of 27,647 (=140+27507) observations in Table 3, Panel B.

Note: Quantitative effects in italics reported in Panel A are based on statistically insignificant coefficients.

FIGURES

FIGURE 1
Net State NBER SOI Mortgage Subsidy Rate by U.S. State in %, 1984-2007

Notes: The series are the NBER SOI average net state mortgage subsidy rate (MSR) in each state and year and show the state-level mortgage interest subsidy rate. The series are generated based on a large, fixed, representative sample of U.S. taxpayers (the income distribution is held fixed), and only vary due to changes in federal and state tax laws that affect specifically state-level income tax structure. States not pictured do not have a state-level MSR during the time period considered. All graphs are normalized to a range of 5 percentage points, except Oklahoma, which has a range from 0 to 7 percentage points.

Notes: Simulation of equation (4): The Impact of implementing a MID subsidy of 26% on the discounted NPV of homeownership by holding period (N) and transactions costs (ϕ) as a percent of house value. **Bold NPVs** highlight negative values. To simulate equation (4), we assume a mortgage interest rate, market interest rate and discount rate each equal to 7%, a mortgage tax subsidy rate equal to the PSID sample average of 26%, a nominal house price appreciation rate equal to 5%, and a property tax rate equal to 2%. Assuming a market LTV of 80%, for a \$200,000 house purchase price computed over a 20 year horizon, the discounted NPV of the mortgage tax subsidy equals \$59,271. Similarly, for a \$600,000 house purchase price, the discounted NPV of the subsidy equals \$177,830. Loan amounts are amortized assuming the household has a fixed level of savings available for a down payment, equal to 20% of the pre-subsidy purchase price, and letting the LTV rise. In other words, the increase in the market price due to the subsidy is rolled into the post-subsidy loan amount and generates a higher LTV, which for all cases above equals 84.6%.
