

The principle of targeting in the presence of local externalities

December 13, 2022

Abstract

We study optimal consumption taxes when the magnitude of an externality varies with the individuals who cause them but taxation is uniform across consumers, e.g. urban fuel consumers generate a larger local externality than rural consumers but face the same fuel tax. We provide a condition for the validity of the targeting principle, according to which the externality only falls on the tax on the externality generating commodity. When this condition holds, one can decompose this tax into an equity/efficiency contribution, an average Pigovian tax and a summary statistics for the heterogeneity in externalities. An empirical application shows that the average Pigovian tax explains most of the fuel tax in France.

JEL classification numbers: H21, H23, D12, Q53, Q54.

Keywords: targeting principle, local externality, pollution, Pigovian tax, commodity taxes.

1 Introduction

The importance of externalities from consumption often depends on individual characteristics of the consumers. In Griffith et al. (2017) one marginal unit of ethanol contained in alcohol generates a greater social damage when it is consumed by heavy drinkers because of increased risks of major health problems or significant injuries sustained in automobile accidents. A similar pattern with a marginal social damage increasing in sugar consumption applies in Dubois et al. (2017). The social damage also varies across consumers in the case of fuel consumption because there is a nonlinear dose relationship between pollution and mortality for traffic related pollutants (Arceo et al., 2016). This follows from vehicle heterogeneity in per-liter emissions of carbon dioxide and local pollutants (Knittel and Sandler, 2018) and the fact that more people are exposed in dense urban areas (Knittel et al., 2016). All these examples feature ‘local’ externalities from consumption: unlike the most widely studied ‘global’ (atmospheric) externalities for which the social damage from consumption is the same across consumers, they involve some heterogeneity in both the exposure and contributions of different consumers to externalities. Our paper studies the optimal design of consumption taxes in the presence of local externalities, putting the emphasis on the circumstances where one can deal with these externalities by taxing externality-generating commodities only.

Optimal taxation in the presence of externalities is the topic of a large literature. The recent studies by Cremer, Gahvari and Ladoux (2010), Jacobs and de Mooij (2015), or Jacobs and Van der Ploeg (2019) focus on the interplay between optimal environmental and labor income taxes when individual heterogeneity primarily relies on labor ability. Instead we focus on externalities varying with the individuals who cause them. First-best remedies then consist of personalized Pigovian taxes: those who cause a greater social damage should face higher prices. Heavy drinkers and sugar consumers should face greater ethanol and sugar prices, and a higher fuel tax should be set on urban drivers using old heavily polluting vehicles. However differentiating taxes across taxpayers often is difficult to implement in practice. One may think of political economy considerations, legal rules based on horizontal equity criteria that limit the possibility of non-uniform treatment of taxpayers, uncontrolled reselling operations from untaxed consumers, or the mere feasibility to observe the whole alcohol and sugar consumption of every individual, and to track drivers closely as practical obstacles to the use of

such taxes.

The seminal theoretical contribution of Diamond (1973) characterizes the second-best optimal uniform tax applying to local externality-generating goods assuming that ‘clean’ consumption goods (those goods that do not imply externalities) are constrained to remain tax-free. It shows that, under this assumption, the suitable tax correction departs from the total marginal social damage in the population to account for individual heterogeneity in the contributions to social damage.

Still the assumption of untaxed clean goods seems very restrictive: in general, one should instead expect the government to play with taxes on both dirty and clean goods to remedy for local externalities, as in Green and Sheshinski (1976) and Eckerstorfer and Wendner (2013). For instance, it is often argued that the government should encourage the consumption of, say, healthy food products and public transportation services by setting lower taxes on these items to promote substitution to dirty goods. Then the whole set of taxes, rather than those on externality-generating goods only, is used as a remedy for externalities. This is much in contrast with the recommendation of the ‘targeting principle’ obtained by Sandmo (1975) and generalized by Kopczuk (2003) that stipulates that a global externality only falls on the tax on the commodity generating it.

Our paper delineates theoretical circumstances where the targeting principle also applies to local externalities. This requires to extend Diamond (1973) by allowing for taxes on every good, either clean or dirty. We find that the targeting principle not only calls for a Pigovian tax correction, as in Kopczuk (2003), but also an additional correction that accounts for the heterogeneity in local damages. This finding is much in accordance with Diamond (1973) recommendations.

An intuition for the validity of the principle of targeting proceeds as follows. In the presence of local externalities, the government would like to discourage specifically the consumption of dirty goods from consumers causing the greatest damage. But the existence of complementarity or substitution across goods is not enough to yield a failure of the principle. The principle will typically fail as soon as a tax on a clean good substitute/complementary to the dirty good allows the government to better target these consumers. If, for instance, urban drivers are the only ones who can access alternative public transportation services, e.g., buses or subway lines, these services should be taxed at a lower rate than in the absence of local externalities from fuel combustion, to incentivize modal shifts away from driving in urban areas.

A unique fuel tax, by contrast, would be less efficient at reducing pollution specifically in urban areas since it would apply to every driver, either urban or rural. In this example one should depart from the targeting principle because a lower tax on public transportation reduces the consumption from the urban greatest polluters without affecting the consumption of the rural least polluters. We show that, if, instead, any other tax performs as well as the fuel tax itself in reducing specifically the fuel consumption of the greatest polluters, then the targeting principle applies. This condition is trivially satisfied in the presence of global externalities, since then the damage from one unit of the externality-generating good does not vary across consumers. In the presence of local externalities, it is satisfied when consumers have the same preferences, but it may also apply even though consumers have different tastes, thus generalizing the scope of the targeting principle in Sandmo (1975), Bovenberg and van der Ploeg (1994) or Kopczuk (2003).

This result is consistent with the rules of optimal taxation obtained by Micheletto (2008) in the presence of local externalities when labor income can be taxed nonlinearly following the Mirrleesian tradition. We instead consider a linear anonymous uniform tax treatment of labor, which prevents any possibility for the fine accommodation for individual heterogeneity in how agents cause and/or suffer from externalities that is enabled by nonlinear income taxes. If high labor income earners are the greatest polluters through, e.g., commuting to work, a higher marginal tax rate on top labor income acts as a socially useful fiscal device by targeting the greatest polluters. Still our condition for targeting share a flavor very similar to those obtained by Micheletto (2008). This suggests that the fiscal rules that should be applied to externality-generating goods may not closely depend on the flexibility of income taxes.

When the targeting principle applies, the second-best optimal fuel tax appears as a sum of three components reminiscent to Diamond (1973) tax recommendation: *(i)* an efficiency/equity term that obeys a version of the many-person Ramsey rule derived by Diamond and Mirrlees (1971), *(ii)* a Pigovian part designed to deal with the total marginal social damage in the population, and *(iii)* a sufficient statistics that aggregates agents' heterogeneity in the external effects that their dirty good consumption is causing. This last component reflects the possibility to discourage specifically the dirty good consumption from the greatest polluters. With this third component, the optimal tax correction can be greater than the marginal social damage: this happens when the fuel consumption from the greatest polluters is more

sensitive to an increase in the fuel price than the consumption from other agents.

A second contribution of our paper is to provide a first empirical assessment of the validity of the targeting principle, illustrated on fuel consumption in France in 2010:2011. We recover the marginal social damage from rural and urban consumers consistent with the assumption that the observed tax system socially optimal. We find a greater social damage caused by urban fuel consumers: a 163% first-best Pigovian tax should be applied on fuel consumed in urban areas, whereas rural consumers should face a much lower tax of 78%. This huge heterogeneity in damages appears consistent with targeting: the available indirect taxes do not allow the tax authority to find a way to discourage specifically the fuel consumption of the greatest polluters from urban areas. This shows that the familiar argument reported above in favor of lower taxes on public transportation services does not apply in France. In fact there is no pollution social concern behind the low taxes on these items. This surprising result relates to the level of aggregation of categories of taxed commodities to which the government refers when setting the taxes. In France, most transportation items other than fuel are grouped within the same category subject to a common reduced (low) VAT rate. ‘Public’ transportation thus consists of every collective means of transport, including urban metro and city buses as well as long distance buses, trains and air transportation services.

The relevance of the targeting principle allows for a clear decomposition of the overall 131% fuel tax applied in France. Eventually we find 16 percentage points that can be imputed to equity/efficiency embodied in the many-person Ramsey considerations, while the remaining 115 points mostly correspond to Pigovian considerations. The importance of environmental concerns in the fuel tax echoes the 2007 Grenelle de l’Environnement agreement in a period when air pollution was identified as a major environmental risk to health (see, e.g., the 2012 World Health Organization decision to classify particulate matter as carcinogen). In return, the third consideration related to agents’ heterogeneity in the external effects that their dirty good consumption is causing was not recognized as a social issue in France over this period.

The paper is organized as follows. Section 2 describes the general setup and Section 3 characterizes the first-best policy. Section 4 gives the optimal second-best consumption taxes and identifies the theoretical circumstances where the targeting principle holds true. Section 5 is devoted to the empirical illustration.

2 Theoretical setup

The economy consists of a continuum of consumers, one representative competitive firm and the government. Consumers are divided into a discrete number H of groups or types indexed by h . There are n^h consumers of type h in a total unit size population. The preferences of every type h consumer are represented by the utility function

$$u^h(\mathbf{x}, y, \ell) - \varphi^h(\mathbf{e}), \quad (1)$$

where $\mathbf{x} \in \mathbb{R}_+^I$ is a bundle of $I \geq 1$ clean consumption goods (that do not imply externalities), $y \in \mathbb{R}_+$ is the consumption of an externality generating good and $\ell \in \mathbb{R}_+$ is labor. The function u^h takes values in \mathbb{R} and satisfies standard monotonicity and convexity properties.

Good y is a dirty good implying an externality entering the utility function through the H -dimensional vector \mathbf{e} whose h -th component is $e^h = n^h y^h$, where y^h is the quantity of the dirty good consumed by one type h agent. The function φ^h is increasing in each component of \mathbf{e} which makes the consumption of the dirty good detrimental to every agent. In the main strand of the literature the function φ^h is usually chosen symmetric in its arguments; often it depends on the aggregate consumption of the dirty good only (see, e.g., Sandmo, 1975; Cremer et al., 1998; Cremer et al., 2003; Sandmo, 2011). Such a representation is well suited to capture global ‘atmospheric’ externalities such as global warming. Indeed it may be that aggregate greenhouse gas emissions from automobile-based fuel consumption differ in rural and urban areas but the origin of the emission in fact is irrelevant for assessing the global warming external impact on welfare.

When φ^h depends on the aggregate consumption of the dirty good only, the role played by the index h in φ^h is to allow for heterogeneity in how much agents suffer from global externalities. This could for instance accommodate for global warming causing a greater damage in rural areas constrained to adapt to new agricultural models.

The main theoretical innovation of our paper is to deal with a more general formulation that represents that some people will impose larger marginal external costs on society. When the function φ^h is asymmetric in its arguments, the identities of dirty good consumers matter to assess both how much a given type h of agents is suffering from the externality and the overall extent of the social damage this type is causing. We especially have in mind situations where local externalities make a given type h consumer exposed to

the externality caused by other type h consumers while being not concerned at all by the externality caused by agents with types $h' \neq h$. The consumption of automobile services in urban areas plausibly affects urban households to a greater extent than fuel combustion from rural areas, whereas the pollution from fuel combustion in rural areas is likely to have only a limited social damage in both urban and rural areas. This kind of situations can be captured by a function φ^h with a partial derivative for a urban type h with respect to the aggregate fuel consumption of urban households that is greater than its derivative in the aggregate fuel consumption of rural households; in the same way, the partial derivative of φ^h for a rural type h with respect to the aggregate fuel consumption from urban households could be set to about 0. The asymmetry in the function φ^h thus appears to be crucial to account for local externalities. Another important case that fits our formulation has an external cost identical for everyone but equal to a sum of an increasing convex transformation of individual consumptions. In this case, those with a higher consumption impose a higher marginal cost on the society. This case applies to the examples of alcohol, tobacco or sugar consumption discussed in introduction.

Our setup also deals with taste heterogeneity through the function u^h that governs consumption patterns, which permits a rich variety of consumption behaviors. For instance, referring again to rural and urban types of agents, heterogeneity in (u^h) allows urban households to consume less fuel and more public transport services than rural households. The geographical distribution of the population represented by (n^h) then gives rise to a profile \mathbf{e} where pollution typically differs in rural and urban areas. In view of the heterogeneity in φ^h it is possible that rural households do not really care about the high pollution in densely populated urban areas but suffer from global warming to a greater extent than the rest of the population.

The only restriction in individual preferences comes from the assumed separability of the external impact $\varphi^h(\mathbf{e})$ on utility. Our formulation implies that the externality influences neither consumption nor labor, which precludes a possible feedback where the demand for fuel would be partially determined by pollution.¹

¹In practice policies that release public information about pollution to encourage the adoption of cleaner modes of transport and heating methods rely on such a kind of feedback. While plausible, the impact of pollution on consumption patterns and labor choices is likely to be of limited importance compared to the impact of prices and income. So far, there is few empirical assessment of this impact. The recent study by Zhang et al.

On the production side we consider a standard linear technology such that every unit of clean (resp., dirty) good j (resp., y) requires using a_j (resp., a_y) units of labor, whatever the externalities. Hence producer prices will be fixed in a competitive equilibrium.

In the Ramsey tradition the government has to finance a given public deficit $R > 0$. The available tools are linear consumption (excise) taxes and income taxes and transfers. With fixed producer prices, choosing consumption taxes amounts to choose consumer prices. The presence of local externalities makes personalized consumer prices necessary to decentralize a first-best allocation. In the sequel we derive an optimal tax rule in a second-best world where taxes are required to be type-independent. This rule will be the basis for the empirical illustration on French data.

3 First-best benchmark

3.1 First-best optimum

Let β^h be the (given) social weight applying on every consumer of type h . The first-best optimum is a profile $(\mathbf{x}^h, y^h, \ell^h)$ and a vector of external effects \mathbf{e} maximizing the social objective

$$\sum_h n^h \beta^h [u^h(\mathbf{x}^h, y^h, \ell^h) - \varphi^h(\mathbf{e})]$$

subject to the feasibility constraint

$$\sum_h n^h \ell^h \geq \sum_j a_j \sum_h n^h x_j^h + a_y \sum_h n^h y^h + R \quad (2)$$

and subject to the form of the externality-generating process

$$e^h = n^h y^h \text{ for all } h.$$

The first-order conditions associated with labor and clean good j yield the familiar equalities between the marginal rates of substitution and the

(2017) finds that some Chinese consumers may reorient consumption to expensive healthy products during pollution events. The adjustment in labor supply is difficult to identify since economic activities influence both pollution and labor demand (see Hanna and Oliva, 2015).

marginal rates of transformation,

$$-\frac{\partial u^h}{\partial x_j} = a_j \frac{\partial u^h}{\partial \ell} \text{ for all } j \text{ and } h. \quad (3)$$

The first-order conditions associated with labor and the dirty good are similar, up to the adjustment required to account for the external effects,

$$-\frac{\partial u^h}{\partial y} = \left(a_y + \sum_k n^k \frac{\beta^k}{\rho} \frac{\partial \varphi^k}{\partial e^h} \right) \frac{\partial u^h}{\partial \ell}, \quad (4)$$

where ρ is the (positive) Lagrange multiplier associated with the feasibility constraint (2). The adjustment from the marginal rate of transformation a_y that appears in (4),

$$\sum_k n^k \frac{\beta^k}{\rho} \frac{\partial \varphi^k}{\partial e^h},$$

equals the social damage caused by a marginal increase in the aggregate consumption of the dirty good by type h . In the presence of local externalities captured by the asymmetry properties of the individual damage function φ^h , different types of consumers typically cause different social damages.

3.2 Personalized Pigovian taxes

The government can achieve the first-best optimum in a decentralized setup by appealing to a set of consumer prices (q_j) for clean goods and personalized consumer prices (q_y^h) for the dirty good, provided that it can also use lump-sum personalized income taxes and transfers (T^h). In equilibrium the assumption of a linear technology implies that the producer price p_j is equals to a_j for every clean good j and similarly the producer price p_y is a_y for the dirty good. Given consumer prices, income transfers, and the profile \mathbf{e} of externalities, a type h consumer chooses consumption (\mathbf{x}, y) and labor ℓ that maximize

$$u^h(\mathbf{x}, y, \ell)$$

subject to

$$\sum_j q_j x_j + q_y^h y \leq \ell + T^h. \quad (5)$$

Let $\mathbf{q}^h = ((q_j), q_y^h)$ be the vector of consumption prices. The demand for consumption goods ($\xi_j^h(\mathbf{q}^h, T^h)$) and $\xi_y^h(\mathbf{q}^h, T^h)$ and the labor supply $\ell^h(\mathbf{q}^h, T^h)$

solutions to this program are such that the budget constraint (5) is satisfied at equality and

$$-\frac{\partial u^h}{\partial x_j} = q_j \frac{\partial u^h}{\partial \ell} \quad (6)$$

for every clean good j , and

$$-\frac{\partial u^h}{\partial y} = q_y^h \frac{\partial u^h}{\partial \ell}. \quad (7)$$

The corresponding indirect utility is $v^h(\mathbf{q}^h, T^h)$.

From (3) and (6), the decentralization of the first-best optimum requires $q_j = p_j = a_j$ for every clean good j . As is usual, commodity taxes on clean goods are useless to decentralize the first-best optimum. From (4) and (7) the consumer prices of the dirty good must be set so that

$$q_y^h = a_y + \sum_k n^k \frac{\beta^k}{\rho} \frac{\partial \varphi^k}{\partial e^h} \text{ for all } h.$$

Since $p_y = a_y$ the first-best Pigovian taxes on the dirty good equal

$$t_y^h = q_y^h - p_y = \sum_k n^k \frac{\beta^k}{\rho} \frac{\partial \varphi^k}{\partial e^h} \quad (8)$$

for every type h . The tax that should be paid by a consumer increases with the social damage that this type is causing. In the plausible case where emissions from fuel consumption cause a greater marginal social damage in densely populated urban areas, the government should set higher Pigovian taxes on fuel consumed by urban households. This applies to the extent that the consumers affected by emissions are socially favored (β_k is high) and hurt by type h consumption.

4 Second-best taxation

In practice it may be difficult to implement personalized taxes on fuel. Indeed legal fiscal rules often have to satisfy some principle of equality before taxation that severely restricts the possible use of non-anonymous consumption taxes. In France regional governments can adjust the TICPE (Taxe Intérieure sur la Consommation de Produits Énergétiques) part of the fuel

tax chosen by the central government, which stands around 60 cents per liter, by an amount that is limited to ± 0.73 cents per liter. Actually most regions choose not to implement any local modulation of the national tax, thus making the fuel tax about uniform over the whole territory. Even in the absence of such legal restrictions it seems unlikely that the central government is able to control where fuel consumption actually takes place. It would be possible to control where fuel is bought but this does not necessarily coincide with the geographical origin of local pollutants emissions: think of a driver purchasing gasoline in a rural area to travel to the neighboring city. For these reasons we now adopt the second-best viewpoint that the government can only rely on anonymous fiscal tools: neither personalized lump-sum income taxes nor personalized Pigovian taxes can be used.

4.1 Optimal discouragement

Let (\mathbf{q}, T) be the vector of consumption prices and income transfer² faced by every type of consumers. The tax authority chooses (\mathbf{q}, T) maximizing

$$\sum_h n^h \beta^h [v^h(\mathbf{q}, T) - \varphi^h(\mathbf{e})]$$

subject to the budget constraint that the net collected taxes finance the public expenditures R ,

$$\sum_j (q_j - p_j) \sum_h n^h \xi_j^h(\mathbf{q}, T) + (q_y - p_y) \sum_h n^h \xi_y^h(\mathbf{q}, T) \geq R + T, \quad (9)$$

with $\mathbf{e} = (e^h)$ and

$$e^h = n^h \xi_y^h(\mathbf{q}, T) \text{ for all } h.$$

Let λ be the Lagrange multiplier associated with the budget constraint (9). The first-order condition associated with the optimal income transfer T is

$$\sum_h n^h \beta^h = 1, \quad (10)$$

²In our setup labor is chosen as the untaxed numeraire while every consumption good is taxable. This modelling choice is equivalent to choosing a tax system where one consumption good is the untaxed numeraire and a linear tax applies to labor, as in Jacobs and van der Ploeg (2019). The transfer T in our setup can be viewed as a (renormalized) basic income.

where

$$b^h = \frac{\beta^h}{\lambda} \frac{\partial v^h}{\partial T} + \sum_k t_k \frac{\partial \xi_k^h}{\partial T} - t_y^h \frac{\partial \xi_y^h}{\partial T} \quad (11)$$

equals the change in social welfare implied by a small increase in an income transfer that would be designed specifically for a type h consumer. The tax t_k on good k in (11) equals the difference $q_k - p_k$ between consumer and producer prices. We shall use b^h as the actual social valuation of a type h consumer. The formula (11) shows that this valuation reflects three different considerations. First it integrates intrinsic considerations driven by the weights (β^h) that appear in the social welfare function: as expected, a high intrinsic valuation β^h of type h translates into a high social valuation b^h . Second, the social valuation of a type h rises when a (fictitious) targeted income transfer toward this type would yield a higher taxes (on both clean and dirty goods). This happens if the type h demand for normal goods displays a significant income effect. The third consideration relies on the last term in (11), which depends on the Pigovian tax t_y^h defined in (8). This accounts for the fact that an income transfer toward type h would also affect the externality caused by these consumers: everything else equal, a type h consumer causing a high social damage (measured by a high Pigovian tax t_y^h) has a low social valuation.

Let ξ_i stand for the aggregate consumption of good i (clean or dirty), a function of (\mathbf{q}, T) . Using (10) and (11), the first-order condition in q_i can be written

$$\sum_k \sum_h n^h t_k \frac{\partial \hat{\xi}_i^h}{\partial q_k} = \sum_h n^h b^h \xi_i^h - \sum_h n^h \xi_i^h + \sum_h n^h t_y^h \frac{\partial \hat{\xi}_y^h}{\partial q_i}, \quad (12)$$

with Hicksian (compensated) demand indexed by a hat. From (10), with $\mathbf{b} = (b^h)$, we introduce

$$\text{cov}(\mathbf{b}, \boldsymbol{\xi}_i) = \sum_h n^h b^h \xi_i^h - \sum_h n^h \xi_i^h,$$

evaluated at (\mathbf{q}, T) solution to (12). Hence the optimal discouragement on good i appearing in the left-hand side of (12) can be rewritten as given in Proposition 1.

Proposition 1. *The optimal tax rates (t_j) on clean goods and the optimal*

tax rate t_y on the dirty good are such that, for all i ,

$$\sum_{j \neq y} t_j \frac{\partial \hat{\xi}_i}{\partial q_j} + t_y \frac{\partial \hat{\xi}_i}{\partial q_y} = \text{cov}(\mathbf{b}, \boldsymbol{\xi}_i) + \sum_h n^h t_y^h \frac{\partial \hat{\xi}_y^h}{\partial q_i}. \quad (13)$$

In the absence of externality, the personalized pigovian taxes t_y^h defined in (8) are all 0, so that the last sum in (13) is zero for every good i . Let (t_i^R) be the Ramsey tax rates that would be optimal in this situation, i.e., the tax rates (t_i) satisfying

$$\sum_{j \neq y} t_j^R \frac{\partial \hat{\xi}_i}{\partial q_j} + t_y^R \frac{\partial \hat{\xi}_i}{\partial q_y} = \text{cov}(\mathbf{b}, \boldsymbol{\xi}_i) \quad (14)$$

for all i . Formula (14) is the usual Diamond and Mirrlees (1971) many-person Ramsey recommendation to equalize the discouragement index of good i in the left-hand side of (14) and the ‘distributive factor’ of this good, measured by the covariance $\text{cov}(\mathbf{b}, \boldsymbol{\xi}_i)$. Demand for good i should then be discouraged by the tax system when consumers who like this good (those types h that have a high consumption ξ_i^h of good i) also have a low social valuation (a low b^h).

Externalities enter (13) through the last sum,

$$\sum_h n^h t_y^h \frac{\partial \hat{\xi}_y^h}{\partial q_i},$$

which represents the marginal social damage caused by the change in fuel consumption following a small change in the price of good i . This sum is positive if the dirty good is a Hicksian substitute to good i for the types of consumers causing the greatest social damage. A lower tax on good i then yields a lower consumption of the dirty good from these agents, and so a lower social damage. The sole environmental considerations then recommend to encourage the demand for good i . On the contrary, the sum will be negative if the dirty good is a Hicksian complement to good i for these agents.

4.2 A scope for the targeting principle

Proposition 1 suggests that every tax should typically depart from Ramsey recommendations in order to exploit complementarity and substitutability

with the dirty good. The existing literature however has shown that the separability in (1) ensures the validity of Sandmo targeting principle when externalities are global: only the tax on the dirty good should then depart from its many-person Ramsey level. This section identifies circumstances where the targeting principle still holds in the presence of local externalities.

To this aim it is useful to refer to

$$\text{cov}(\mathbf{t}_y, \mathbf{s}_i) = \sum_h n^h t_y^h s_i^h - \sum_h n^h t_y^h,$$

where \mathbf{t}_y is a vector with t_y^h as h -th component, and \mathbf{s}_i is a vector whose h -th component

$$s_i^h = \frac{\partial \hat{\xi}_y^h}{\partial q_i} \bigg/ \frac{\partial \hat{\xi}_y}{\partial q_i}$$

is the relative sensitivity of type h fuel consumption with respect to the price of good i . The formula (13) for optimal taxes then rewrites

$$\sum_{j \neq y} t_j \frac{\partial \hat{\xi}_i}{\partial q_j} + \left(t_y - \sum_h n^h t_y^h - \text{cov}(\mathbf{t}_y, \mathbf{s}_i) \right) \frac{\partial \hat{\xi}_i}{\partial q_y} = \text{cov}(\mathbf{b}, \boldsymbol{\xi}_i). \quad (15)$$

The scope of the targeting principle immediately follows from (15).

Proposition 2. *The targeting principle holds if $\text{cov}(\mathbf{t}_y, \mathbf{s}_i)$ is independent of i ,*

$$\text{cov}(\mathbf{t}_y, \mathbf{s}_i) = \phi \text{ for all } i. \quad (16)$$

Then the taxes on clean goods should be set to their Ramsey levels, i.e., $t_j = t_j^R$ for every clean good j , while the tax on the dirty good y is

$$t_y = t_y^R + \sum_h n^h t_y^h + \phi. \quad (17)$$

By rewriting this condition as

$$\sum_h t_y^h \frac{\partial \hat{\xi}_y^h}{\partial q_i} = \left(\phi + \sum_h n^h t_y^h \right) \frac{\partial \hat{\xi}_y}{\partial q_i}, \quad (18)$$

we see that it is satisfied when the reaction of the social damage to a change in the price of good i (in the left-hand-side of (18)) can be expressed as

a given proportion, independent of the good i under consideration, of the reaction of the aggregate fuel consumption. Hence we shall refer to (16) as a ‘sensitivity-neutral’ condition.

As expected, this condition is satisfied in the two polar cases where the personalized Pigovian taxes (t_y^h) are uniform across types, which happens if the externality is global ‘atmospheric’, or if agents have the same preferences (u^h is independent of h) since then they all have the same demand function for the dirty good. In each of these two polar cases, the covariance ϕ in (16) is zero. Still, a novel insight from Proposition 2 is to show that the targeting principle may even be satisfied when agents generate different local externalities and have heterogeneous tastes. Indeed (16) holds with ϕ both non-zero and identical across goods: this is what happens when agents have different homothetic preferences, as shown in Example 1 below.³

Example 1. The utility function of a type h agent in (1) takes the special form

$$u^h(\mathbf{x}, y, \ell) = u(\mathbf{x}, y, \theta^h \ell),$$

where individual heterogeneity is captured by the real parameter θ^h that weights labor disutility. If $u(\cdot)$ is homothetic, i.e.,

$$u(\lambda \mathbf{x}, \lambda y, \lambda \theta^h \ell) = \lambda u(\mathbf{x}, y, \theta^h \ell) \text{ for all } \lambda > 0,$$

then the compensated demand for fuel can be written as

$$\hat{\xi}_y^h(\mathbf{q}, u^h) = \varphi(\mathbf{q}) u^h$$

for some function φ of prices. In this specification,

$$\frac{\partial \hat{\xi}_y^h}{\partial q_x} = \frac{u^h}{\sum_k n^k u^k} \frac{\partial \hat{\xi}_y}{\partial q_x}, \quad \text{and} \quad \frac{\partial \hat{\xi}_y^h}{\partial q_y} = \frac{u^h}{\sum_k n^k u^k} \frac{\partial \hat{\xi}_y}{\partial q_y}.$$

As a result $s_i^h = s^h$ for every good i and thus the condition (16) for the targeting principle is met, $\text{cov}(\mathbf{t}_y, \mathbf{s}_i) = \phi$ for all i . We have $\phi \neq 0$ as long as the external effect varies across consumers. \square

Example 1 shows that the principle of targeting holds if Engel curves are linear. The importance of this class of individual preferences has already

³Appendix A provides a parametric example where the sensitivity-neutral condition instead is not met.

been emphasized by Jacobs and van der Ploeg (2019) in the global externality case.

When the sensitivity-neutral condition holds, the tax on the dirty good should be adjusted from its many-person Ramsey level in order to reflect both the average social damage in the population,

$$\sum_h n^h t_y^h$$

and the heterogeneity driven by local externalities captured by ϕ . The fuel tax should be set above the average social damage if the fuel consumption of the households implying the greatest social damage is the most sensitive to a change in the fuel tax, $\phi > 0$.

If an accurate estimate of the social damage \mathbf{t}_y caused by the dirty good consumption were available, (18) could be directly used to assess the empirical validity of the sensitivity-neutral condition. This strategy would be closely in line with the strand of research effort initiated by Parry and Small (2005) for collecting data about all possible external effects from fuel consumption. Otherwise, if an accurate estimate of the social damage \mathbf{t}_y instead is lacking, this strategy is difficult to pursue. Our empirical illustration develops an alternative strategy to test for the validity of the sensitivity-neutral condition (18) based on the recovered perceived damage by the government of France.

5 An illustration on data from France

5.1 Empirical strategy

Our aim is to provide a decomposition of the fuel tax in France based on Proposition 2. Our empirical analysis relies on the assumption that the French government chooses a tax on fuel that maximizes social welfare of French households. To this purpose we proceed in two steps:

1. We recover the social valuations (b^h) and the personalized Pigovian fuel tax rates (t_y^h) that would make the current observed tax rates optimal and thus satisfy (10) and (13). To this purpose we estimate a complete demand system on 10 broad categories of consumption goods including fuel. Demand is assumed to fit an Almost Ideal Demand System (AIDS)

formulation which is a flexible enough function to approximate at the second-order any demand system (Barnett and Seck, 2008), and so allows us to deal with the first-order conditions (10) and (13) in the neighborhood of the observed taxes.

2. Given the recovered Pigovian taxes (t_y^h) and the AIDS price elasticities, one can compute $\text{cov}(\mathbf{t}_y, \mathbf{s}_i)$ and assess the empirical validity of the sensitivity-neutral condition (16). If valid, the computation yields an estimate of the summary statistics ϕ . Given the actual fuel tax t_y formula (17) can then be used to get the Ramsey component t_y^R . This yields a decomposition of the actual fuel tax t_y into a many-person Ramsey and a Pigovian part adjusted for household heterogeneity ϕ in the damage their fuel consumption is causing.

The existing literature delivers little consensus about a precise evaluation of global and local social marginal damages caused by fuel consumption. Our methodology involves recovering these damages from the observed tax system. While it is rather common in the public finance literature to deduce the social valuations of various groups of taxpayers from the observed tax system (see, e.g., Bourguignon and Spadaro, 2012), it is less usual to use this system to get estimates of the external costs. In our context (8) shows that the social valuations of the different types of individuals affect the magnitude of the external costs, so that it could be hazardous to postulate given external costs of fuel consumption in order to recover the social valuations.⁴

In the first step we use consumption microdata from the French consumer expenditure ‘Budget de Famille’ survey to estimate AIDS elasticities.⁵ We rewrite the first-order conditions (13) in Proposition 1 in function of budget shares and price elasticities,

$$-\sum_k \frac{t_k^{\text{val}}}{1+t_k^{\text{val}}} \sum_h n^h \frac{q_k s_k^h}{q_i \xi_i} \hat{\varepsilon}_{ki}^h = 1 - \sum_h n^h b^h \frac{q_i \xi_i^h}{q_i \xi_i} - \sum_h n^h \frac{t_y^h}{q_y} \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h, \quad (19)$$

⁴In Section 5.5 we perform an exercise similar to the one made in the main strand of the literature, following Parry and Small (2005). We use data collected from public administrative reports to get estimates of the external costs. The results fall in a range comparable to those we obtain following our estimated damages methodology.

⁵An early estimation of the AIDS on the Budget de Famille survey can be found in Nichele and Robin (1993).

where

$$\hat{\varepsilon}_{ki}^h = \frac{q_i}{\xi_k^h} \frac{\partial \hat{\xi}_k^h}{\partial q_i} \text{ for all } k, i \text{ and } h$$

is the type h price elasticity of compensated demand for good k with respect to the price of good i , and excise taxes (t_i) are related to valorem tax rates (t_i^{val}) by

$$\frac{t_i}{q_i} = \frac{t_i^{\text{val}}}{1 + t_i^{\text{val}}}. \quad (20)$$

Given expenditures in the current (observed) situation and AIDS price elasticities, the system of equations formed by (10) and (19) is linear in the unknown social valuations (b^h) and the Pigovian tax rates (t_y^h/q_y) for all h . Estimates (\hat{b}^h) and (\hat{t}_y^h/q_y) of these unknown parameters are obtained by minimizing the sum of the squared differences between both sides of (10) and (19). As a by-product of (11), we can also get the estimated type h intrinsic social valuation

$$\frac{\beta^h}{\lambda} \frac{\partial v^h}{\partial m^h} = \hat{b}^h - \sum_i \frac{t_i^{\text{val}}}{1 + t_i^{\text{val}}} \frac{q_i \xi_i^h}{m^h} \varepsilon_{im}^h + \frac{\hat{t}_y^h}{q_y} \frac{q_y \xi_y^h}{m^h} \quad (21)$$

where m^h is her disposable income.⁶

At this stage we will have all the information needed to start the second step of our empirical analysis and assess the empirical relevance of the sensitivity-neutral condition (16). To this aim, note that the writing of (16) in the form (18) can also be expressed in terms of expenditures and price elasticities,

$$\sum_h n^h \frac{t_y^h}{q_y} \frac{q_y \xi_y^h}{q_i \xi_i^h} \hat{\varepsilon}_{yi}^h = \left(\sum_h n^h \frac{t_y^h}{q_y} + \frac{\phi}{q_y} \right) \sum_h n^h \frac{q_y \xi_y^h}{q_i \xi_i^h} \hat{\varepsilon}_{yi}^h. \quad (22)$$

Given expenditures and price elasticities, once Pigovian taxes (t_y^h) are replaced with their recovered values (\hat{t}_y^h), the only remaining unknown ϕ/q_y in

⁶This procedure generically leads to different estimated marginal damages for urban ($h = u$) and rural ($h = r$) consumers, i.e., $\hat{t}_y^r \neq \hat{t}_y^u$, even if actual tax rates are not differentiated between urban and rural consumers. Indeed, from the first-order conditions (19), the system is overdetermined as long as the rank of the matrix of the coefficients of (b^h) and (t_y^h/q_y) has a rank greater than four.

(22) can be estimated by running the OLS regression

$$\sum_h n^h \frac{\hat{t}_y^h}{q_y} \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h = \varphi_0 + \varphi_1 \sum_h n^h \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h + \zeta_i \quad (23)$$

in a sample with $I + 1$ (the number of categories of clean items, plus the dirty good) observations, with ζ_i a residual. The assumption that (18) holds for every good is considered as being satisfied if the model (23) provides us with a good fit to the data with a zero OLS estimate $\hat{\varphi}_0$ of φ_0 . Under this condition we can decompose the optimal fuel tax t_y as in (17).

5.2 Data

Our data comes from the French consumer expenditure survey ‘Budget de Famille’ realized by the National Institute of Statistics (INSEE) in 2011. The survey reports household final expenditures on consumption items disaggregated at the 5-digit COICOP international classification, as well as information on various household demographic and spatial characteristics. Households were surveyed from October 2010 to September 2011. They were divided into six different groups and all the households in the same group were surveyed during the same time wave. This yields price variability over time and space sufficient to estimate demand functions accurately.

Our initial sample consists of 10,342 households living in continental France. From this sample we select observations where the family head is between 18 and 80 years old, is not self-employed, and we remove observations in the bottom and top 1% of the income (total expenditures) distribution. We are eventually left with a dataset of 8,722 observations.

Local pollution through NO_2 mostly concerns densely populated and urbanized areas of France.⁷ We therefore form two groups of households referring to the size of the population of the area where they live (τ variable of the survey) with a population threshold of 500,000 inhabitants. By convention, ‘urban’ households live in the most populated areas while the remaining households are ‘rural.’ With this threshold urban areas comprise the 17 largest French cities, the threshold corresponding approximately to the population in the urban area of Avignon in 2010. The variation across space of

⁷ NO_2 concentration is highly correlated with local external effects from fuel consumption since NO_2 in the air primarily is due to the burning of fuel.

the mean NO_2 and PM_{10} concentration levels are very well explained by this population threshold.⁸

Household characteristics and the time wave when they are surveyed are reported in Tables **Menage** and **Depmen** of the survey while Table **C05** gives us household expenditures for every 5-digit COICOP category. Categories that are considered as less flexible are treated as given household demographic characteristics (see, e.g., Blundell, Pashardes and Weber, 1993, for a similar treatment). This applies to items reported as durables in the COICOP international classification, as well as the whole 2-digit COICOP category Housing, water, electricity, gas and other fuels (COICOP category 04), which mostly comprises rents paid by tenants. The French survey does not provide imputed rents for landlords but it reports in an original category numbered 13 various housing related payments that do not enter the usual COICOP categories, including landlord expenditures, e.g., mortgage interest. These payments are included into fixed (landlord) expenditures to treat tenants and landlords symmetrically. Finally prices about Health (COICOP category 06) and Education (COICOP category 10), which are mostly publicly provided in France, are often missing and cannot be accurately computed. These two categories are therefore also considered as fixed expenditures. We are eventually left with 10 broad 2-digit COICOP categories: Food (01), Alcoholic beverages, tobacco and narcotics (02), Clothing and footwear (03), Furnishings, household equipment and routine household maintenance (05), fuel (0722), Transport (07 except 0722), Communication (08), Leisure and Culture (09), Restaurants and hotels (11) and Other goods and services (12).⁹ Our Transport category consists of the whole original COICOP 07 category net of both durables, e.g., , and fuel expenditures. It includes expenditures on passenger rail, air or marine means of transport, all taxed at the reduced (low) VAT rate, as well as car repair and maintenance items taxed at the standard (high) rate.

Prices obtain from the table **Carnets** which reports both quantities and expenditures on disaggregated fine 5-digit COICOP items for every household. We abstract from issues related to quality measurement and directly compute Stone price indexes from unit values (the ratios of expenditure to quantity). For every aggregate consumption category, the indexes are com-

⁸See Appendix C for more details.

⁹This classification neglects complementarity/substitution between labor and fuel consumption.

puted as a function of the region (`zeat` variable) broken down by population size¹⁰ (`tau` variable), and time wave of the survey.¹¹

Tax data for every 5-digit COICOP item are obtained from the Institut des Politiques Publiques (Meslin, 2012). In France most items are subject to the VAT or excise taxes. The standard (high) rate of VAT in 2011 was 19.6% while the reduced (low) rate was 5.5%.¹² Both the standard rate of VAT and an excise tax called TICPE (Taxe Intérieure de Consommation sur les Produits Energétiques) apply to fuel: the sum of the net of tax (producer) price and the TICPE is subject to the standard rate of VAT. The amount of TICPE in fact varies according to the fuel type, an information that is missing in the survey. In 2010 the tax rates on the main fuel types stand between 115% for diesel and 160% for (unleaded) petrol; in 2011 the global world rise in the price of energy has implied an increase in the net of tax (producer) prices and so, given the amount of TICPE, implied lower fuel taxes ranging from 97% to 133%. We find a mean fuel tax rate over the overall period equal to 131%.

Table 1: RURAL AND URBAN HOUSEHOLDS IN FRANCE¹

	rural	urban
Number of households surveyed	5,137	3,412
Number of households represented ²	25,854	19,771
Average number of persons per household	2.264	2.254
Average number of units of consumption per household	1.55	1.545
Average age of the head of the household	50.34	47.73
Average household income per year	31,647	36,781
Average total household expenditures per year	25,452	28,447
Average total household flexible expenditures per year	16,172	17,927

1. Computed from the 2011 Budget de Famille survey

2. They obtain from the actual number of surveyed households using the `pondmen` weights provided in the survey. These are used to compute the profile (n^h), e.g., $n^h = 25,854 / (25,854 + 19,771) \simeq 57\%$.

5.3 Descriptive statistics

As shown in Table 1 family structures are similar for rural and urban households. Urban households are younger, richer, and they save more than rural households. They have also higher fixed expenditures (mostly because of housing) so that the total expenditures for flexible categories tend to be

¹⁰The survey considers 11 brackets but prices are often missing in sparsely populated rural areas, so that we have consolidated the three bottom brackets into only one bracket comprising areas with 10,000 inhabitants at most. The other brackets are 25-40 (thousands of inhabitants), 40-50, 50-100, 100-200, 200-500, at least 500, and Paris.

¹¹A great deal of attention has been devoted to cleaning price data. We remove observations in `Carnets` where either the quantity and/or the unit (in kg, liter or unit) is missing. We also remove those where the operation cannot be tracked because the shop where the purchase took place is not filled. To deal with reporting errors, we do not consider observations that correspond to a unit that represents less than 5% of the reported units per 5-digit COICOP category. In the case of fuel, for instance, most households report consumption in liters, but some report units, which sometimes correspond to liters (40–50 units for a fuel tank) and sometimes to one fuel tank (1 unit), both with the same (tax included) price around 50–60 euros. We also remove price and quantity observations in the bottom or top one percent of the observations for every 5-digit category, for each wave and `zeat`×`tau` area. There still remain 1.5% of household observations where some prices are missing. They are usually found in areas with a low number of inhabitants so that some items are not bought at all during the time window of the survey. In these few cases we compute the price indexes at the `zeat` level.

¹²The resulting average tax rates for the 2-digit flexible categories are 5.9% for Food, 66% for Alcohol, 19.6% for Clothing, 19.3% for Furnishings, 15.2% for Transport (other than fuel), 131% for fuel (COICOP 0722), 6% for Communication, 11% for Culture, 5.5% for Restaurants, and 19.6% for Other goods and services.

similar.

Table 2: BUDGET SHARES OF FLEXIBLE CATEGORIES OF GOODS¹

	rural	urban
Food and non-alcoholic beverages (01)	25.5	24.4
Alcoholic beverages, tobacco and narcotics (02)	5.3	4.3
Clothing (03)	7.2	7.5
Furnishings, household equipment and routine household maintenance (05)	3.0	3.4
Transport (except fuels) (07 except 0722)	5.0	7.2
fuels and lubricants for personal transport equipment (0722)	9.2	6.2
Communication (08)	5.2	5.2
Recreation and culture (09)	9.9	10.7
Restaurants and hotels (11)	8.8	11.1
Miscellaneous goods and services (12)	20.9	20.0

Note 1. Budget shares in the total expenditures for flexible categories.

The budget shares of flexible categories given in Table 3 are about identical for the two types of households. The main differences concern the structure of the original COICOP Transport category (which is a consolidated category with both our Transport and Fuel categories). This original category represents about 14 – 15 percent of the budget of every household, but rural households actually devote a much larger share to fuel than urban households. Instead urban households consume more Transport (except fuel), through, e.g., the use of public transportation services.

Note 2. The income elasticity of Food is 0.907.

other goods. The formula for optimal taxes given in Proposition 1 thus suggests that the consumption of goods other than fuel should be encouraged, if any, compared to the situation where there would be no externality from fuel. It is important to observe that Transport and Fuel are substitutes in both urban and rural areas, though a public bus and subway transportation network is typically absent from rural areas. When combined with budget shares data in Table 2, the substitution applies to a lower amount of Transport expenditures in rural areas but displays a positive cross-price elasticity with Fuel of the same magnitude as in urban areas. Substitution in rural areas thus has to involve other means of transport than public bus or subway.

5.4 Empirical results

5.4.1 Social valuations and personalized Pigovian taxes

Table 5 reports the values of the estimates (\hat{b}^h) and (\hat{t}_y^h/p_y) that minimize of the sum of the squared differences between both sides of (10) and (19).¹³ It also uses (21) to provide an estimate for the intrinsic components

$$\frac{\beta^h}{\lambda} \frac{\partial v^h}{\partial m^h}$$

¹³Recovering the social valuation of every type of agents from the observed taxes using the identification assumption that these taxes are optimally chosen by the government to meet its social objective is a standard exercise in applied public finance (see, e.g., Ahmad and Stern (1984) for an early reference). So far it does not seem that this strategy has been applied to the recovering of environmental social damages.

that enter the social valuations (b^h).

Table 5: SOCIAL VALUATIONS AND PERSONALIZED PIGOVIAN TAX RATES

	rural	urban
Social valuation (\hat{b}_h)	1.18	0.81
Pigovian tax rates (\hat{t}_y^h/p_y)	78%	163%
Intrinsic valuation ¹	1.04	0.70
Income effect	0.17	0.15
Pigovian contribution to social valuation	0.03	0.04

Note 1. By (21), Social valuation - Income effect + Pigovian contribution.

Redistribution clearly goes from urban to rural households: the total social gain from a 1 euro income transfer to a rural household equals 1.18 euro and so yields a net social gain of 0.18 euro whereas the same transfer toward a urban household costs 0.19 euro to the society. Although (21) shows that the total social gains (b^h) may give a blurred picture of the intrinsic stance of redistribution in France, the intrinsic social valuations display a similar pattern where rural are relatively favored by the tax system: the society would be neutral regarding the transfer of 1 euro to one rural household whereas this same transfer would cost 0.30 euro if benefiting a urban household.

The income effects in (21) make the total social gain b_h above the intrinsic social valuations since type h agents are also valuable to the government as sources of tax revenues. The first-best Pigovian taxes in the second row of Table 5 represent the values of the social damages that would make observed current taxes optimal. Such damages clearly matter to the society, both in rural and urban areas, as signaled by the very high levels of Pigovian taxes. Using the number of rural and urban households (n^h) reported in Table 1 and the Pigovian tax rates (\hat{t}_y^h/p_y) in Table 5, we find an average social damage from fuel equal to

$$\sum_h n^h \frac{\hat{t}_y^h}{p_y} = 115\%.$$

A large part of the 131 percentage points of the fuel tax thus is imputable to global and the average local externalities over the population. We also find evidence of huge heterogeneity in the social damages perceived by the French government: the first-best Pigovian taxes are twice as large in urban areas as they are in rural areas. One could have expected that this huge spread would reduce a lot the intrinsic social valuation of urban agents compared

Figure 1: with fuel

Figure 2: without fuel

to that of rural agents. But this is not the case: as reported in Table 5, the Pigovian contributions to social valuations in (21),

$$\frac{\hat{t}_y^h q_y \xi_y^h}{q_y m^h},$$

are about identical across households and close to 0. This is due to the fact that the greatest environmental marginal damage caused by urban households comes together with their much lower fuel consumption. This combination suggests that the high differences in the social damages between rural and urban people may not necessarily call for an adjustment ϕ for household heterogeneity in (17). This is what we discuss in the next section.

5.4.2 Targeting principle

We know from Proposition 2 that the validity of the targeting principle relies on the sensitivity-neutral condition (16) or (18) evaluated in the current (observed) situation. We now have all the information needed to assess (18) using the model (23): the distribution of households (n^h) is reported in Table 1, the budget shares are in Table 2, the compensated price elasticities in Tables 3 and 4, and the first-best Pigovian taxes in Table 5.

In a preliminary step we plot the sum that appears in the left-hand side of (22) for every category of goods in the vertical axis of Figures 1 and 2 against the last sum in the right-hand side of (22) in the horizontal axis. Figure 2 abstracts from the outlier representative Fuel point. The fit of (23) in Figures 1 and 2 is impressive. For every good i , the reaction of the aggregate social

damage to a change in the price of i (in the vertical axis) is in the same proportion of the reaction of aggregate fuel consumption to the same price change (in the horizontal axis).

This is confirmed by the OLS estimation of the model (23). The OLS estimate $\hat{\varphi}_0$ of φ_0 in Table 12 indeed is 0 while $\hat{\varphi}_1$ is highly significant in our 10 observation setup.

Table 6: ESTIMATION RESULTS OF THE MODEL (23)

$$\sum_h n^h \frac{t_y^h}{q_y} \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h = \varphi_0 + \varphi_1 \sum_h n^h \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h + \zeta_i$$

Constant $\hat{\varphi}_0$	1.211 $\times 10^{-4}$ (1.231 $\times 10^{-3}$)
Slope $\hat{\varphi}_1$	0.493*** (4.306 $\times 10^{-3}$)
Number of observations	10

Notes: Adjusted R-squared: 0.99
*** Significant at the 1 percent level.

We conclude that the data does not reject the empirical validity of (18). This means that the French government can be viewed as not adjusting the overall tax system in response to the presence of a heterogeneous welfare impact of local pollution across rural and urban areas. In France environmental considerations fall on the fuel tax only.

This finding does not fit the popular idea that low taxes on clean public urban modes of transportation are justified by the social goal of promoting substitution from fuel consumption. An intuition for this finding plausibly rests on the high level of aggregation of consumption categories that we use in our empirical illustration, with a Transport category that does not treat urban modes of transportation, e.g., metro, in isolation. Our consumption data could actually be disaggregated to group items that are mostly consumed in urban areas. This finer level would facilitate the exploitation of substitution between goods to reduce specifically the fuel consumption of

the urban drivers. The issue is whether the government is able to refer to this finer classification when setting the taxes. We argue that in France the observation of a uniform low tax on every alternative mode of transportation, either urban or rural, suggests that the government can only refer to a higher level of aggregation. In Appendix we perform a robustness check in which we split our Transport category into two smaller categories, but we require that every good in each sub-category is taxed at the same rate. This yields a large public transport sub-category and another sub-category with parking charges, car rental expenditures, and car repair and maintenance items. The targeting principle still holds with this finer classification.

One can now use the expression of the $\hat{\varphi}_1$ to obtain an estimated value $\hat{\phi}$ of ϕ . From (22) and (23) we have

$$\hat{\varphi}_1 = \frac{\hat{\phi}}{q_y} + \sum_h n^h \frac{t_y^h}{q_y} \Leftrightarrow \frac{\hat{\phi}}{q_y} = \hat{\varphi}_1 - \sum_h n^h \frac{t_y^h}{q_y} = 0.493 - 0.496 = -0.003.$$

This computation shows that $\hat{\phi}$ is negative but close to 0. The interpretation is that the huge household heterogeneity in the damages (\hat{t}_y^h) they cause tend, if any, to decrease the optimal discouragement of fuel consumption. Nevertheless this consideration eventually turns out to be negligible, and we conclude that only the average Pigovian tax matters in the correction of the fuel tax from its many-person Ramsey level. The reason follows from the results reported in Table 5 where the Pigovian contributions to social valuation are about equal for urban and rural households. The fuel consumption from urban households (who cause the greatest social damage) is more elastic to the fuel price than the fuel consumption from rural households (see Tables 3 and 4), but this is compensated by the lower fuel consumption of urban households (see Table 2).

If one neglects the correction $\hat{\phi} = -0.003$ for household heterogeneity in the damages they cause, the Pigovian part reduces to a weighted average between the first-best personalized Pigovian taxes that should be supported by rural and urban households. It follows that rural households loose from a uniform fuel tax: they face a second-best fuel tax above its first-best level. In return, urban households gain from uniformity restrictions, which echoes the distributive impact found by Knittel and Sandler (2018) on US data.

We are now in a position to get our final decomposition of the fuel tax into the various contributions exhibited in Proposition 2. Switching to ad

valorem taxes and using again $q_y = p_y(1 + t_y^{\text{val}})$, the formula (17) finally gives

$$\frac{\hat{t}_y^{\text{R}}}{p_y} = t_y^{\text{val}} - (1 + t_y^{\text{val}}) \sum_h n^h \frac{\hat{t}_y^h}{q_y} - (1 + t_y^{\text{val}}) \frac{\hat{\phi}}{q_y} \simeq 1.31 - 1.15 = 0.16.$$

The many-person Ramsey tax on fuel thus equals 16 percent, a level that is close to the standard rate of VAT (19.6%). This is consistent with the standard view of VAT on clean goods as dealing with equity and efficiency such as summarized by the many-person Ramsey considerations. In France most of the fuel tax rate of 131% is imputable to externality considerations summarized by a simple population weighted average of Pigovian taxes over rural and urban households.

5.5 Actual and second-best optimal taxes

As is known from, e.g., Coate and Morris (1995), political economy and lobbying considerations sometimes lead to the adoption of inefficient environmental policies. In the US several studies actually find a fuel tax below its optimal level (West, 2004; Parry and small, 2005; Bento et al., 2009; Borck and Brueckner, 2016), but fuel taxes can also be found above their optimal level (Parry and small, 2005). In this section we provide two different assessments of our identifying assumption of optimal taxes in France.

The first assessment relies on a methodology similar to the one used by Parry and Small (2005). This is based on recovering the various the social damages (t_y^h) from fuel consumption from data collected from public administrative reports.¹⁴ The social damage listed in these reports consist of air pollution, congestion, Greenhouse gases emissions and, to a lesser extent accidents and noise (see Table 8 in the appendix). This yields Pigovian taxes reported in the first column of table 7. These taxes are close to our estimated Pigovian taxes under the assumption of optimal consumption taxes, given in Table 5 and reproduced in the second column of Table 7. This finding suggests that 2011 actual and optimal consumption taxes were located close to each other in France.

The second assessment uses the fact that the first-order conditions for optimal taxes make the differences between both sides of (7) and (15) equal to 0. With our data we find that a residual value of 0.018 for the sum of the

¹⁴Details about data sources and conversion operations are provided in Appendix B.

Table 7: PIGOVIAN TAXES

	Direct from administrative report ¹	Our estimate of t_y^h
Urban ²	160%-174%	163%
Rural	32%-103%	78%

Note 1. Source: Gressier and Bureau (2003), table page 25

Note 2. population density greater than 420 inhabitants per km²

squared differences between both sides of (7) and (15) when evaluated at \hat{t}_y^h and \hat{b}^h . We have reproduced a bootstrap exercise 100 times starting from tax rates randomly drawn between the minimum and maximum observed tax rates (0.055 and 1.31), i.e., we have estimated the taxes \tilde{t}_y^h and \tilde{b}^h that minimize the same sum of squares assuming random taxes. The 100 draws average sum of the squared differences between both sides of (7) and (15) is equal to 0.103, which is more than 5 times higher than 0.018. We conclude that the empirical validity of the assumption of optimal taxes in France again does not seem to be rejected by the data.

6 Conclusion

In the presence of local fuel externalities, one would like to discourage specifically the consumption of fuel from consumers causing the greatest pollution damage. If taxing some clean good allows the government to better target these consumers, it is socially profitable to adjust the tax on this good to account for environmental considerations, implying a failure of the targeting principle.

We have provided a theoretical condition such that this principle still applies when local externalities matter, and we have shown that the condition is satisfied in France: there is no way to discourage specifically the fuel consumption of the greatest polluters from urban areas by adjusting taxes on goods other than fuel.

Our theoretical setup is designed to exploit the data available in the Budget de Famille survey. It suffers, however, from several important limitations.

1. The survey does not give information about individual fuel consumption location. We have therefore implicitly assumed that urban and

rural types consume fuel in urban and rural areas, respectively. If available, this information would allow us to distinguish between fuel consumed in urban areas and fuel consumed in rural areas. The fact that the social damage from urban fuel consumers is plausibly lower when they consume fuel in rural areas, could then justify appealing to taxes varying across stations. As far as the gasoline station where fuel was bought can serve as a proxy for fuel combustion location, fuel bought in stations located in urban areas could be taxed more heavily.

2. Our data gives neither the means of transport, private or public, nor the type of vehicle used. In practice one can expect the consumption of collective passenger transport modes in urban areas and cleaner vehicles, e.g., those equipped with diesel particulate filters, to be encouraged by the optimal tax system. Assuming that a finer classification of transport modes is likely to imply a failure of the targeting principle, and provided that the government refers to such a finer classification when designing consumption taxes, it would be worthwhile to study the magnitude of the departure of fuel taxes from the marginal social damage caused by fuel combustion.
3. One important limitation of our data concerns labor effort. The Budget de Famille survey provides us with information about labor income but not the number of hours worked. Following West and Williams (2004) a demand system including leisure could otherwise be estimated, allowing us to account for possible substitution/complementarity between labor and fuel consumption. If, viewing fuel consumption as mostly driven by commuting needs, rural workers consume more fuel than urban dwellers, the targeting principle could fail. Then the recommendation would be to reduce the tax burden on rural workers and to tax fuel more heavily, above its Pigovian level.

Appendix

A The targeting principle in specific cases

In contrast with Example 1 in the main text, here we provide a parametric example that illustrates a failure of the targeting principle.

Example 2. There are two types of agents $h = 1, 2$ whose preferences are on the polluting good y and two clean goods $\mathbf{x} = (x, m)$. Good m serves as an untaxed numeraire. There is no labor disutility. The preferences of type 1 are represented by the utility function

$$u^1(\mathbf{x}, y, \ell) = \log(\inf\{x, y\}) + m.$$

Thus, for type 1, good x is a complement of the polluting good y . With y being fuel, one may think of x as a private transportation service device.

Type 2 utility is

$$u^2(\mathbf{x}, y, \ell) = \log(y) + m.$$

The compensated demand functions

$$\xi_x^1 = \xi_y^1 = \frac{1}{q_x + q_y}, \quad \xi_x^2 = 0, \quad \text{and} \quad \xi_y^2 = \frac{1}{q_y}.$$

From (11), assuming $\beta^1 = \beta^2$, we have $b^1 = b^2$. The two first-order conditions in (15) then rewrite

$$-\frac{n^1 t_x}{(q_x + q_y)^2} + \left(t_y - \frac{n^1 \frac{t_y^1}{(q_x + q_y)^2} + n^2 \frac{t_y^2}{q_y^2}}{n^1 \frac{1}{(q_x + q_y)^2} + n^2 \frac{1}{q_y^2}} \right) \left(-\frac{n^1}{(q_x + q_y)^2} - \frac{n^2}{q_y^2} \right) = 0, \quad (24)$$

$$-\frac{n^1 t_x}{(q_x + q_y)^2} + (t_y - t_y^1) \left(-\frac{n^1}{(q_x + q_y)^2} \right) = 0. \quad (25)$$

In this case, the targeting principle does not apply. The argument proceeds by contradiction. Suppose accordingly that t_y is set at its average value across population, as in Diamond's (1973),

$$t_y = \frac{n^1 \frac{t_y^1}{(q_x + q_y)^2} + n^2 \frac{t_y^2}{q_y^2}}{n^1 \frac{1}{(q_x + q_y)^2} + n^2 \frac{1}{q_y^2}}. \quad (26)$$

It follows from (24) that $t_x = 0$. However, replacing t_x with 0 in (25) yields $t_y = t_y^1$ which contradicts (26) as far as $t_y^1 \neq t_y^2$. The intuition is simple in the case where $t_y^1 > t_y^2 > 0$, i.e., type 1 agents are the greatest polluters. Since these agents are the only consumers of good x , which is complementary to the dirty good, it is socially useful to adjust the taxation of good x for environmental concerns. Note that (24) gives

$$t_y < \frac{n^1 \frac{t_y^1}{(q_x + q_y)^2} + n^2 \frac{t_y^2}{q_y^2}}{n^1 \frac{1}{(q_x + q_y)^2} + n^2 \frac{1}{q_y^2}}$$

at a solution: the tax that should be applied on the dirty good stands below its Diamond's level.

B Direct external costs from administrative reports

In this appendix we apply Parry and Small's (2005) methodology to France. We report in table 8 the constant (real) external costs of passenger vehicles computed by Gressier and Bureau (2003).

Table 8: EXTERNAL COSTS OF PASSENGER CARS¹

	Urban ² (French administration)	Rural/dispersed urban (French administration)
GhG	0.6 ³	0.6
Air pollution	2.9	0.1-1.5
Accident	0.8	0.8
Noise	0.52	0-0.52
Congestion	2.5-3.5	0-1.5

Note 1. Source: Gressier and Bureau (2003), table page 25.

Note 2. Population density greater than 420 inhabitants per km².

Note 3. In euro (base year: 2000) per 100 km.

External costs of GhG and air pollution¹⁵ in the Bureau and Gressier report are based on a value of 7.41 liters per 100km in 2000. We use this

¹⁵Unlike Parry et Small (2005) we assume that air pollution is fuel-related rather than distance-related. The particulate emissions standards of motor engines are indeed in emis-

value to convert external costs from euros per 100km to euros per liter. We use the French GDP growth rate to update these external costs to 2011. This gives external costs in euros per liter for year 2011 that are reported on the first two rows of Table 9.

Available external costs for security, noise and congestion are expressed as distance rather than fuel related. In order to convert these costs to euros per liter, we consider that only 40% of the long-run price responsiveness of fuel consumption is due to changes in vehicle travel, the other 60% being imputed to fuel efficiency (Parry and Small, 2005). We thus multiply the external cost of noise, congestion and accident by 0.4 in order to get the corresponding component in the Pigovian tax. We use the French GDP growth rate to update these external costs to 2011. We use an average fuel consumption per 100km of 7 liters in 2011¹⁶ to convert these external costs from euros per 100km to euros per liter. The corresponding values are reported in the third to fifth rows of Table 9. The total cost from fuel consumption is finally converted from euro per liter to tax rates using an average pump price (including tax) was 1.4 euro per liter¹⁷ in 2011 and an ad valorem fuel tax 131%. This gives the pigovian tax in Table 7.

Table 9: PIGOVIAN TAX COMPONENTS FROM DIRECT EXTERNAL COSTS

	Urban	Rural/disperse urban
GhG	0.114	0.114
Air pollution	0.554	0.019-0.287
Accident	0.064	0.064
Noise	0.042	0-0.042
Congestion	0.202-0.283	0-0.121
Total (euros per liter)	0.976-1.057	0.197-0.628
Pigovian tax rate	160%-174%	32%-103%

sions per km but recent public release scandals about emissions show that these standards are not met in general conditions and that particulate emissions are more plausibly related to the amount of fuel consumed.

C Rural and urban areas from NO₂ concentration

The available data on NO₂ and PM10 in France gives the daily prediction of the surface concentrations between 12/22/2017 and 01/22/2018 by PREV’AIR. The data are available in the form of maps covering metropolitan France at a spatial resolution of about 10km. We map these data with coordinates of localities (Communes). We then use INSEE dataset ‘Base des Aires Urbaines’ to get the `tau` variable corresponding to each Commune in the Budget de Famille survey.¹⁸ Figure 3 plots the mean of NO₂ and PM10 concentration values in all the Communes that belong to an area of a given population size (`tau` variable of the survey). There is a clear jump in average NO₂ and PM10 concentration corresponding to a threshold of 500,000 inhabitants in the area that separates areas with `tau` equal to 09 and 10 (Paris) from smaller areas. The break is confirmed by running linear regressions of NO₂ and PM10 mean concentrations in the Commune on the dummy variables equal to 0 below and one above each possible value of the `tau` variable (see Table 10). The highest R^2 is found for a threshold of 500,000 inhabitants in the area.

Figure 4 gives the whole distribution of frequency of NO₂ and PM10 concentration values for Communes within urban and rural clusters.

¹⁸Here, unlike Section 5.2, we refer to the original 11 category classification of the survey and keep small areas separate. 00 (non-urban area); 01 (below 4,999 inhabitants); 02 (from 5,000 to 9,999); 03 (10,000 to 24,999); 04 (25,000 to 39,999); 05 (30,000 to 49,999); 06 (50,000 to 99,999); 07 (100,000 to 199,000); 08 (200,000 to 499,999); 09 (above 500,000 inhabitants, Paris excepted); 10 (Paris area).

Figure 4: Frequency of NO₂ and PM₁₀ concentration values in the Communes of urban and rural areas

D Finer transport categories

The validity of the targeting principle rests on the property that the use of taxes on clean goods adds nothing to the fuel tax to reduce fuel consumption in urban areas. In the main text our Transport category includes every non durable item other than fuel in the original 07 Transport category of the COICOP classification. Some goods of our Transport category thus are consumed mostly in urban areas, others are consumed mostly by rural households, and there are also goods consumed by the whole population of rural and urban households, e.g., some airplane journey. This modeling choice may plausibly bias the results in favor of the targeting principle by making difficult to play with complementarity and substitution between fuel and other Transport items to single out urban fuel consumers. In this appendix we describe how our results are affected when one considers a finer classification of the original Transport category subject to the institutional constraint that each finer sub-category includes items taxed at the same rate. We split the items of the 07 COICOP category (other than fuel) into one group of goods taxed at the reduced low rate and another where goods are taxed at the standard high rate. The first group includes collective transport expenditures, related to inland, air and maritime modes of transport, including, e.g., bus and subway tickets. The second one consists of parking charges, car rental, automotive spare parts or expenditures on the repair and maintenance of vehicles. If bus and subway networks address specifically urban areas, isolating the second group could facilitate a better targeting of the greatest urban polluters.

To get insights into whether this finer classification of transport items is likely to yield a failure of the targeting principle, we reproduce Figure (2) by plotting the sum that appears in the left-hand side of (22) for every category of goods in the vertical axis of Figure (5) against the last sum in the right-hand side of (22) in the horizontal axis. When compared to Figure (2) we observe that the heavily taxed items in the Transport category is the main driver of the whole Transport category used in the main text. Instead consumption of collective transportation services, taxed at the reduced rate, displays a low sensitivity to changes in the fuel price. Still, the fit of (23) in Figure 5 remains very good, though it is not as good as in the main text. For every good i , the reaction of the aggregate social damage from fuel to a change in the price of i (in the vertical axis) appears to be in the same proportion of the reaction of aggregate fuel consumption to the same price change (in the

Figure 5: Validity of the fuel tax decomposition with finer Transport categories

horizontal axis). This ensures the validity of the targeting principle in the presence of finer transport categories. Table 12 shows that the OLS estimate $\hat{\varphi}_0$ of φ_0 is 0 while $\hat{\varphi}_1$ is highly significant in our 11 observation setup.

Table 12: ESTIMATION RESULTS OF THE MODEL (23)

$$\sum_h n^h \frac{t_y^h}{q_y} \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h = \varphi_0 + \varphi_1 \sum_h n^h \frac{q_y \xi_y^h}{q_i \xi_i} \hat{\varepsilon}_{yi}^h + \zeta_i$$

Constant $\hat{\varphi}_0$	2.395 $\times 10^{-3}$ (3.355 $\times 10^{-3}$)
Slope $\hat{\varphi}_1$	0.395*** (3.943 $\times 10^{-2}$)
Number of observations	11

Notes: Adjusted R-squared: 0.92
*** Significant at the 1 percent level.

The lower fit (R^2 is equal to 0.92 instead of 0.99) is consistent with the intuition that the (low) tax on public modes of transport singles out urban consumers. The validity of the targeting principle allows us to use $\hat{\varphi}_1$ to obtain an estimated value $\hat{\phi}$ of ϕ . From (22) and (23) we have $\hat{\varphi}_1 = -0.06$. This negative correction reflects a too high discouragement of the rural fuel consumption when the government sets the average Pigovian tax. As a result, the optimal fuel tax must be adjusted downward with respect to the average Pigovian tax.

Eventually we find a Ramsey tax of 40%, a pigovian part of 98% and a correction for rural/urban heterogeneity equal to -6%.
